Integrative Pain Medicine

Jeanne Taylor Hernandez

OVERVIEW HISTORY AND RATIONALE FOR BEHAVIORAL PAIN MEDICINE

The effect of emotions and life events on health has been described since the 1800s, by Freud in the psychoanalytic literature, Alexander in the psychosomatic literature, and Selye (1978) in the physiology literature. As 60%–90% of doctor visits are currently estimated stress to be related (Benson, cited in Wallis, 1998), it would seem that psychosocial issues have an impact on physical symptoms such that a psychologist could find work in a busy hospital clinic almost any day. In fact, two-thirds of primary care physicians report difficulty finding mental health care for the estimated 40% of patients needing some form of mental health treatment, but fewer than 10% of patients follow through, even when a provider is identified for them—due to either the perceived stigma associated with seeking such treatment or difficulty making a separate appointment and getting to the appointment (Cummings, Cummings, & Johnson, 1997). However, when mental health providers are conveniently located in physicians' offices, some 90% of referred patients do enter treatment (Cummings et al., 1997). As patients in chronic pain clinics usually have more mobility and financial problems than primary care patients, we would expect their rate of follow-through to be even lower.

The American Psychological Association (APA) and the American Medical Association recently brought

integrative health care to our attention, and they have recently worked together to offer diagnostic codes for psychologists who treat medical patients so that they can bill appropriately for their time. Their focus in moving integrative health care forward in this era of increased specialization is on cost-effectiveness as well as improved patient care. The *APA Monitor* and the *Register* (published by the National Register of Health Services Providers in Psychology) have recently and regularly described the integration of psychologists into various disciplines of medicine, including primary care and palliative care.

In 2001, the Accreditation Council of Graduate Medical Education required residency programs to develop programs on integrative collaboration in patient care, including team-building skills and partnering skills, with other professionals in health care. Residents are required to learn how and when to refer to psychologists; to do this, they must learn from mental health providers how thinking style, memory, and emotions influence health; how social and cultural influences affect health care utilization; and how their interactions with patients can affect compliance. Furthermore, they must learn to integrate this information into their own medicinal discipline.

The Accreditation Council of Graduate Medical Education (2007) also requires pain fellowship programs to “provide educational experience in common psychiatric and pain co-morbidities, which include

substance-related, mood, anxiety, somatoform, factitious, and personality disorders” with programs that “provide educational experience in the effects of pain medications on mental status. The fellow must understand the principles and techniques of the psychosocial therapies, with special attention to supportive and cognitive behavioral therapies, sufficient to explain to a patient and make a referral when indicated. Faculty must be psychiatrists or clinical psychologists who have documented experience in the evaluation and treatment of patients with chronic pain.” To meet this requirement, some programs hire psychologists to practice with and teach fellows about the psychological aspects and management of pain and about how to evaluate it. Training includes daily participation in collaborative conversations about clinic patients, monitoring of a selected group of pain patients with multiple psychosocial and medical problems who are followed by the psychologist, and lectures on the topics discussed in this chapter.

WHY IS THE INVOLVEMENT OF BEHAVIORAL MEDICINE IMPORTANT TO THE TREATMENT OF PAIN?

Pain as a Public Health Concern

First of all, treating mental health problems when and where they exist appears to improve health care utilization and public health in general. Overall, personal health care costs appear to rise when stress and depression are not treated (Goetzel, Anderson, Whitmer, Ozminkowski, Dunn, & Wasserman, 1998). For example, in the treatment of patients with heart disease, psychosocial interventions reduce the risk of subsequent heart attacks by 75% compared to medical treatment alone. In fact, research in the rapidly growing field of positive psychology shows that a positive versus negative mindset has a significant effect on both pain and disease. In 2008, the American Psychosomatic Society devoted its annual scientific meeting to “Liaisons in Psychosomatic Medicine: Fostering Interdisciplinary Research and Integrative Patient Care.” The National Institutes of Health, a major funding source for health-related research, supports holistic medicine enough that it awards significant funding for mind-body, alternative, and integrative therapies. And yet, as we will discuss, health insurance companies, including Medicare and Medicaid, are still reluctant to pay for treatments that are not strictly Western medicine. This has deterred hospitals from sponsoring integrative medicine even in their rehabilitation

programs. Now, as health care costs are being recognized as a major issue at political, personal and corporate levels, it is time to demonstrate how integrative medicine can and should work, and to demonstrate its cost-effectiveness.

Pain Is Designed to Be Unpleasant

Second of all, let us remember that pain is a basic survival tool that makes us uncomfortable enough to notice a problem that we might otherwise ignore. Pain awareness engages the cognitive problem-solving part of the brain in a plan to resolve tissue damage. Specifically, nociception is an unconscious process of messaging about tissue damage through the nervous system, as opposed to pain, which is the conscious awareness of nociception, or “a complex, compelling unpleasant bodily awareness normally associated with tissue trauma” (Chapman, 2005, p. 158). Biologically, pain is a cascade of neurotransmitter and biochemical responses to nociception involving the HPA axis and the limbic system that causes changes in blood pressure and blood sugar, serotonin, and norepinephrine levels, affecting concentration, mood, behavior, healing, and sleep. Unfortunately, in the case of chronic pain, there is no need for the pain. If it continues, the cascade of responses just described can go on to cause permanent change and damage in other physiological and psychological systems.

The Effect of Stress on Pain and Vice Versa

Third, prolonged physical stress can result in “super system dysregulation” (Chapman, Tuckett, & Song, 2008, p. 122), and treating only the original physical symptom does not address this or the underlying psychological issues. Chronic pain usually involves overlapping emotional pain (Gatchel, 2005) and psychological stress, and suffering can lead to the same cascade of physiological stress responses (Rossi, 1993), making diagnosis and treatment challenging for physicians working without a psychologist. The affective (cognitive and evaluative) components of pain are processed in the emotional areas of the brain (see Derbyshire, Whalley, Stenger, & Oakley, 2004; Peyaron, Laurent, & Garcia-Larrea, 2000; Vogt, Berger, & Derbyshire, 2003; Vogt, Derbyshire, & Jones, 1996), causing a variable amount of distress. This helps to explain why some events, physical or otherwise, cause more pain to some people than to others (Chapman & Gavrin, 1999). As the patient’s quality of life goes down, so may his or her income, independence, and ability to carry out social and

family responsibilities. Dealing with this and treatment protocols can be additionally stressful, as the patient's various caregivers (lawyers, family, doctors, for example) are often interested in different outcomes, leading to conflict, confusion, and stress for the patient, who is juggling appointments and the requirements of a family, two or three health care providers, Social Security or worker's compensation attorneys and adversaries, and mortgage lenders (Gatchel, 2005). Psychological support and counseling can make a very big difference to overall well-being.

Two pain disorders demonstrate the mind-body and brain mechanisms of pain fairly well. Complex regional pain syndrome (CRPS) is a disorder that may begin with a minor injury that should heal but instead leads to excruciating pain, muscle atrophy, and bone demineralization. CRPS appears to be sympathetically driven. There appear to be some psychological precursors, including anxiety and post-traumatic stress disorder. Treatment can include some psychotherapy for management of anxiety, as patients often disclose a series of emotional events that trigger a fight-or-flight or psychophysiologically defensive response. Nociception and the psychological meanings attached to it can trigger the brain to temporarily rewrite the neurosensory map of the pained area, leading to a relative neglect of that limb, which is a dissociative process that leads to pain and distress symptoms (Galer, Butler, & Jensen, 1995; Maihofner, Handwerker, Neundörfer, & Birklein, 2003; Moseley, 2004). The process of neglect is a dissociative process beginning at a deep level. In light of research on hypnotizability and psychosomatic disorders, we might suspect that highly hypnotizable people may be more likely to develop CRPS under the right conditions, and also that hypnosis may help them resolve the CRPS. The other pain disorder responding to the strategy of psychologically addressing brain mechanisms is phantom limb pain, which can come from damage in the nerve endings at the stump or in the spinal cord, or from a change in the somatosensory cortex map of the body in response to missing sensory input from the lost or paralyzed limb, or from a peripheral nerve injury that leads to lack of sensation (Melzack, 1992). This can take the form of pain (Wall, 1999). With some assistance, the patient may learn to change the sensation from negative to positive once he or she understands that the pain is generated by his or her brain, not the stump or paralyzed limb.

Psychological pain therapy aims to soothe the physiological responses and the emotional responses of fear and suffering related to negative expectations about future pain. The value of cognitive-behavioral therapy

(CBT) techniques in treating chronic pain is well known and well documented (see Keefe, Caldwell, Williams, & Gil, 1990; Kirsch, Montgomery, & Sapirstein, 1995; Lefort, Gray-Donald, Rowat, & Jeans 1998). Pain patients treated with CBT spend less on health care, have better quality of life, experience less pain, and take less sick time than those who do not have any therapy (Linton & Nordin, 2006). Hypnosis can effectively relax and comfort the patient, alter the physiological responses to nociception (alleviate pain), and help lower the patient's resistance to incorporating pain coping strategies (see chapter 24). Recent reviews of the effectiveness of hypnosis in treating pain and medical problems are outlined elsewhere (Hernandez, 2010).

Pain That Is Psychosomatically Generated or Perpetuated

The fourth rationale for approaching pain as a psychological event is that it is necessary to investigate whether the pain may have actually begun as an emotional event. Teasing this out is difficult due to the intricate overlap of emotional and physical aspects of chronic pain, and even more so when the medical model instead of a holistic or psychosomatic (*psyche* = mind; *soma* = body) one is being used. Surgeons and pain specialists know that physical injury and disease cannot fully predict the amount of pain that one experiences. Other determining factors are concurrent anxiety and traumatic events, context of the injury, depression, negative expectations, social support, numerous other personality factors and cognitive styles, and one's potential for suffering. Suffering usually trumps injury as a pain event, and pain can become a metaphor for a life experience. Pain psychologists routinely ask their patients about traumatic or other notable experiences concurrent with the onset of pain (Cassell, 1991; Keefe, LeFebvre, Maixner, Salley, & Caldwell, 1997).

Depression and anxiety often go hand in hand with chronic pain, and also with trauma (Levin, Lazrove, & van der Kolk, 1999; Roy-Byrne, Smith, Goldberg, Afari, & Buchwald, 2004). The percentages of chronic pain and disease patients with histories of child abuse are impressive. In one study, 53% of female chronic pain patients had been physically or sexually abused, and those patients showed more somatization and greater utilization of the health care system (Haber & Roos, 1985). Other studies show that child abuse in its various forms leads to a greater likelihood of poor health habits, including smoking, STIs and obesity, ischemic heart disease, chronic bronchitis, hepatitis, and

skeletal fractures (Felitti et al., 1998, in a survey of general practice patients); lung disease; peptic ulcers; arthritic disorders; cardiac disease; diabetes; autoimmune disorders; thyroid dysregulation; depletion of endogenous supplies of dopamine, serotonin, and norepinephrine; high blood sugar and cholesterol; and hampered memory and cognitive functions (Goodwin & Stein, 2004; Salomons, Osterman, Gagliese, & Katz, 2004; Rossi, 1993; van der Kolk, 1997, 1994; Yehuda, Giller, Southwick, Lowy, & Mason, 1991). Also, trauma of any sort often heightens pain sensitivity (Plesh, Gansky, Curtis, & Pogrel, 1999) and can lead to somatization and unexplainable pain (Casey, Greenberg, Nicassio, Harpin, & Hubbard, 2008; Walker et al., 1997). This may depend upon whether or not the abuse is therapeutically processed (Haugaard, 2004; Ray, 2004; Scaer, 2001; van der Kolk, 1994; Wickramasekera, 1988; Wilson, van der Kolk, Burbridge, Fisler, & Kradin, 1999). Fifty percent of female irritable bowel syndrome chronic pain patients reported prior abuse: 40% report child abuse, 28% adult abuse, and 33% repeated abuse (Green, Flowe-Valencia, Rosenbaum, & Tait, 2001). Irritable bowel syndrome and pelvic pain patients have been shown to be likely to have coexisting mental and somatoform disorders and histories of sexual and physical abuse, leading some to wonder if the disorders are more alike than distinct (Matheis, Martens, Kruse, & Enck, 2007). All this is of concern to the patients, their health care providers, and the public health community. Children whose mothers experienced trauma and developed somatization symptoms are at greater risk of developing somatization symptoms themselves (Craig, Cox, & Klein, 2004). Especially for chronic pain patients, PTSD should be treated early in order for treatment to be maximally effective.

WHEN THE PSYCHOLOGICAL CARE IS THE PAIN TREATMENT

Psychological pain management is a specialty unto itself. Milton Erickson often said that if one can have phantom pain, one can have phantom pleasure, indicating the plasticity of the interpretation of nociceptive signals. The fifth reason, then, for bearing in mind the two-way pathways between pain and suffering, pain and attitude, pain and mind-set, and pain and emotional state is so that all possible psychological facets of pain can be addressed at the onset of medical treatment. A thorough description of psychological pain treatment approaches and protocols fills many books and may be reviewed elsewhere. A number of attitudes, mind-sets,

types of past experiences, and personal factors relevant to successful pain management include the following (Hernandez, in press).

Education about illness can address old beliefs about pain and illness that may or may not be true but nonetheless have been lodged in one's mind at various times in one's life. Most devastating are the stereotypes about aging, disability, pain, and outcomes of specific medical problems. Also problematic is the belief that use of the medical model is the only way to relieve pain; patients should be advised to consider alternative medicine and self-healing practices, if only to encourage proactivity. A psychologist may need to help patients cope with the loss of friends who no longer include them in their plans and help them establish new social networks, as these are important for well-being. Pain, illness, and disease seem to have negative connotations, and the people's interpretations of illness can lead many to steer clear of those with disease or disability. As social roles begin to change, patients may need help seeing themselves as just as worthy and important as they were before. Research shows that the most significant predictor of successful outcomes in therapy is the patient-therapist relationship—even when the only therapy is medication. This also applies to the relationship between the patient and his or her medical doctor, particularly when the medical problem has an emotional component, the symptoms are subjective, and two-way communication can make a difference in the treatment approach. What the physician treats is partly determined by how well the patient communicates his or her problem; likewise, what the physician says has a bearing on how the patient feels. The psychologist can often improve on those interactions by serving as a translator or facilitator, particularly if the patient is not compliant with prescribed treatment program. The overall physical condition of the patient before the chronic pain began may factor into his or her well-being, as well as deconditioning that occurred as an aftermath and worsened pain. Psychologists can monitor nutrition, weight, exercise, and other relevant lifestyle factors during treatment. Feeling that they have a life purpose shapes how patients feel about themselves and puts everything else into perspective. Psychologists often help patients develop new life purposes or modify old ones.

Psychologists can also spot patients' primary and secondary gains related to pain. Regarding primary gains, an estimated 50% of primary care visits are not even about the patient's initially complaint but are rather an attempt at some level to draw attention to another problem. In cases of litigation, some providers prefer to wait until after litigation has ended to treat pain,

as patients find it easier to let go of pain they do not need to demonstrate. Secondary gains are the benefits or positive aspects of an adverse situation that may make moving out of the situation unattractive, no matter how bad it might be. For example, chronic pain or disabled patients may no longer be required to work or carry out other responsibilities. Patients may fake or exaggerate pain after accidents for financial or situational gain; this is sometimes unconscious and the result of having to fight for the right to compensation. Psychologists often work with worker's compensation and disability offices to help determine who can or cannot work.

Many attitude factors determining control of pain are amenable to therapy, including feelings of empowerment versus helplessness regarding pain. Patients with an internal locus of control take ownership of the outcomes in their lives, believing that they have primary influence over what will happen and what they can accomplish. Those with an external locus of control are inclined to believe that their futures are determined by other people, chance, or powerful religious forces. Those with an internal locus of control who take an active role in their health care are better able to make the changes necessary to manage pain and maintain health (Wallston & Wallston, 1982). So important to pain control is the client's coping style that some pain clinics have prospective patients see a mental health provider on the first visit. In fact, a positive or negative interpretation of a situation partially determines the outcome. Recent medical and psychological research on positive and negative thinking shows that positive attitudes and mind-sets have a powerful effect on well-being, healing, and longevity. Negative thinking is related to depression, which is related to physical pain. Some patients cope with medical problems by learning more about them, while others avoid any details and want the doctor to fix the problem (avoidance style of coping). As chronic pain is not often fixable, this is not ideal. Motivational interviewing can help establish the patient's role on his or her own health care team and keep him or her actively involved in treatment (Jensen, Nielson, & Kerns, 2003). Patients may need to grieve over the loss of a former lifestyle, sense of security, and old friends. A flexible thinking style (versus a fundamentalist mind-set) helps modify self-image and lifestyle. Patients with a religious or spiritual belief system who believe in a system greater than themselves and take life events less seriously often do better with adverse events such as pain. Finally, patients who are psychologically minded and recognize the power of the conscious and unconscious mind to resolve problems may have better success with CBT and hypnotic protocols and may be more willing to engage in treatment.

Depression, anxiety, and stress all worsen pain, as they can cause body tension and affect pain perception. Chronic pain can make patients more susceptible to depression, especially those already prone to it or going through stressful times. Patients often experience anxiety or panic, not knowing what to expect for the future, fearing the pain will worsen or not go away, worrying about employment, finances, and relationships. Some overreact during pain exacerbations, which is known as "catastrophizing" (Sullivan, Bishop, & Pivik, 1995). PTSD is the common aftermath of a traumatic event such as an injury. Psychologists can address arousal symptoms such as sleep disturbances, irritability, outbursts of anger, or difficulty concentrating, persistent thoughts, and nightmares.

INTERDISCIPLINARY PAIN CLINICS

Definitions

Multidisciplinary medicine is practiced by groups of health care providers working together as resources and referrals to and for one another. Participating physicians may have team meetings or refer patients to one another; they may share clinic space. Samuel So described opening his multidisciplinary clinic in this way: "It took a lot of donuts and latte at first, but soon my colleagues saw a lot of personal benefits for our patients and for ourselves as well" (Stanford Hospital and Clinics Medical Staff Update Online, 2004).

Integrative medicine describes the incorporation of alternative and complementary techniques into health care practice to improve patient care and treatment outcome. It is defined by the Committee on the Use of Complementary and Alternative Medicine by the American Public Board on Health promotion and Disease Prevention (2004) as "the practice of medicine that reaffirms the importance of the relationship between practitioner and patient, focuses on the whole person, is informed by evidence, and makes use of all appropriate therapeutic approaches, health care professionals and disciplines to achieve optimal health and healing."

Interdisciplinary medicine describes the practice of providers working together to concurrently treat a specific problem or patient, such that each one's services complement and may depend upon the outcome of the others', and the patient knows he or she is being treated by a team.

"Dovetailing services" describes a treatment plan that melds two or more providers' treatments into one well-sequenced plan. It can be most efficient and cost

effective when all participating providers see the patient on the same day or before any of them make their final treatment decisions. Belar and Deardorff (2009) point out the importance of a collegial and close working relationship among pain practitioners and health care providers in general, which gives the institution the reputation of providing state-of-the-art treatment and offers the patient a sense that he or she is seen, known, and cared for holistically. Patients seem to appreciate this, as may be seen in the results of a telephone survey that asked patients, "Do you believe that doctors should join their patients in prayer if the patients request it?" to which 64% responded yes (MacLean et al., 2003).

Interdisciplinary pain practices involve many treatment modalities that see pain and disability as the result of intertwining of biological, physical, psychological, and social mechanisms that should be addressed together.

The last 40 years saw Fordyce, Bonica, and other clinicians move the pain management field forward with clinical and research psychologists onboard. Cross-disciplinary interest in pain actually began back in the 1940s, when Alexander described the psychosomatic process and developed the field of psychosomatic medicine. The discipline focuses specifically on how what begins as an emotional or environmental event may become a physiological one that affects physical health. The reverse is also true: what starts out as a physiological, immune, or biochemical disorder can lead to an emotional disorder with social and physical consequences, all of which exacerbate that original pain or disease process. Physical health can affect us emotionally before we see the physical symptoms, manifesting in depression, lack of interest or motivation, and the overall sickness response (Chapman & Gavrin, 2008), just as emotional stress exacerbates pain and illness. The first psychosomatic diseases defined by Alexander were irritable bowel syndrome, inflammatory bowel disease, ulcerative colitis, asthma, and allergies. Both Alexander and Sigmund Freud saw how psychological stressors can result in psychogenic pain or conversion disorders, although as psychoanalysts, they primarily directed their attention to the unconscious suppression of emotional issues that patients' conscious minds could not tolerate. Not surprisingly, as the intestinal track is so responsive to stress, one of the first cross-disciplinary groups to teach psychosomatic medicine was at the University of Rochester, where internists such as John Romano and George Engel studied GI disorders (see Engel, 1977).

In the late 1940s, Bonica in Washington and Alexander in Texas recognized the benefit of several disciplines,

including mental health professionals, working together to resolve chronic pain. In communication with each other, the doctors independently set up the first ongoing groups to tackle pain problems and weathered the difficulties of such groundbreaking endeavors. Interest grew here and abroad. While the first pain clinic actually opened in Japan in 1962, it was Bonica's (1953) ongoing dedication to the field that spawned the first multidisciplinary approach, which stressed the importance of treating and researching the psychological issues related to pain. The chronic pain centers in Washington and Texas spawned research, teachings, and publications, leading to a period of profound growth in multidisciplinary medicine through the 1970s to 1990s. As early as 1979, four types of pain clinics were defined:

Major Comprehensive Pain Center, with the space and personnel to evaluate the interactions between the biopsychosocial (biological, psychological and sociological) components of chronic pain and develop a treatment plan to resolve them [15% of pain clinics in 2001] Comprehensive Pain Center, with organized space and individuals to manage pain, but not to fully evaluate or treat it [28%] Syndrome-oriented Pain Center, which lacks the facility or personnel to treat all aspects of pain or all types of pain, [35%] and Modality-Oriented Pain Center, which specializes in treating a certain aspect of pain [22%]. (from Loeser, 2001)

Pisetsky, Keram, and Drossman (1992) describe setting up an interdisciplinary clinic to diagnose and treat functional bowel pain and dysfunction at University of North Carolina–Chapel Hill. They point out that such collaborations take time to build but eventually become more efficient than referring patients from one practice to another. They discuss the clinic's growing pains and their acquisition of trust and respect among colleagues who learned to feel comfortable with their own expertise and ignorance and overcame the temptation to scrimp on time by bypassing the interdisciplinary approach on busy clinic days. Training included interviewing techniques for the diagnosis of functional disorders, along with the psychological, sociological, and family dynamics that are interlaced with disease. They initially worked with a psychiatrist and later on with a psychologist. The model is still employed (Gerson & Gerson, 2003). In such clinics that treat chronic pain and disabled patients, inadequate compensation and poor payers mix, often leading to funding problems. When psychotherapy sessions are minimally reimbursed and take place according to standard time slots, perhaps psychologists' greatest benefit has to be seen as their consultation to physicians.

While Bonica and others' ideal was for patients to be holistically treated by all disciplines together, a survey of self-identified pain clinics shows that (1) psychological management is still usually done separately from medical treatment and (2) that treatment is more likely to be interdisciplinary when the pain physicians learned that approach during their fellowships. The multidisciplinary pain treatment model is described by Frey and Fordyce (1983) and by Turk, Meichenbaum, and Genest (1983). The interdisciplinary chronic pain and rehabilitation model, larger in scope, includes a number of specialists (an anesthesiologist, physiatrists, physical and occupational therapists, psychologists, psychiatrists, nutritionists, and social workers, for example) working toward comprehensive rehabilitation; the team is led by one or two people, and team members communicate or consult with one another, working or meeting together. Recently, Turk (2007) reviewed outcome data for patients receiving care from such programs as opposed to other care. He found that pain reduction and activity level of patients in interdisciplinary programs were as good as or better than that of patients receiving standard medical treatment; that there were fewer iatrogenic complications, less medication use, and less health care utilization; and that more patients returned to work. Other studies compare psychological treatment for chronic pain favorably to more invasive measures and to opioid use (Brox et al., 2003; Martell, O'Connor, Kerns, Morales, Kosten, & Fiellin, 2007; Merrill, 2003; Turk, 2002). Turk's (2007) riveting review of the statistics on invasive measures showed that 56% of surgeries are to correct previous surgical complications, 68% of surgical patients report worse pain after surgery, 56% say that their symptoms are no better after surgery, and 43% of spinal cord stimulator (SCS) implantations result in serious complications. A recent systematic Cochrane review concluded that cognitive intervention combined with exercise is recommended for chronic low back pain (van Tulder, Koss, Seitsalo, & Malmivaara, 2006). There is also strong evidence that intensive multidisciplinary biopsychosocial rehabilitation improves function compared with inpatient or outpatient non-multidisciplinary treatments (Guzman, Esmail, Karjalainen, Malmivaara, Irvin, & Bonbardier, 2001). Gatchel and Okifuji's (2006) review showed that comprehensive pain programs incorporating the services of physicians, psychologists, and physical therapists offer the most efficacious and cost-effective evidence-based treatment for persons with chronic pain. This is particularly noteworthy in that such clinics usually treat the patients with the most serious and complex overlay of pathology that their other providers cannot handle.

Specifically, Tollison, Kriegel, and Satterthwaite (1989) showed that in the group of patients attending a comprehensive pain program, the percent of patients using opioids went from 69% to 22% in a year, whereas for the ones not attending such a clinic, the percent using opioids dropped only from 81% to 75%. Given the negative effect of opioids on the body over time, the benefit of this to health care utilization and well-being is extraordinary. In terms of disability, Seres, Painter, and Newman (1981) showed that with comprehensive pain treatment the percent of patients on disability decreased from 70% to 45% and that even the majority of litigation cases were closed within 1 year. Return-to-work rates following comprehensive pain treatment range from 29% to 86%, whereas strictly medical treatment rates average 27% (Guzman et al., 2001). A comparison study of treatment of low back pain with surgery versus comprehensive pain management showed that surgery was not cost effective at 2-year follow-up (Rivero-Arias, Campbell, Gray, Fairbank, Frost, & Wilson-MacDonald, 2005), and that there was no better pain relief (Fairbank, Frost, Wilson-MacDonald, Yu, Barker, & Collins, 2005). Furthermore, there are fewer surgeries for low back pain when comprehensive pain programs are available (Rasmussen, Nielsen, Hansen, Jensen, & Schioetz-Christensen, 2005).

Most surgeons understand that pathology cannot predict pain, and pain physicians are often unable to identify the pathophysiology leading to pain. Comprehensive or interdisciplinary clinics are based on the biopsychosocial understanding of pain and disability as a dynamic interaction of physical, psychological, and social factors that keep a cycle of misery going. Given the evidence, we might expect less invasive and less costly treatments to become the preferred option of patients, providers, and insurance companies. However, the difficulty getting third-party payers to reimburse adequately for such care has led some comprehensive clinics with psychological and physical therapy providers to abandon this therapeutic approach.

DOVETAILING SERVICES IN INTEGRATIVE MEDICINE

Looking to develop a definition of integrative health care, Boon, Verhoef, O'Hara, and Findley (2004) did an extensive literature review and described many models of integrative programs and clinics in the United States and Canada. They saw that services designed to integrate conventional and alternative medicine were more fragmented than seamless, and not ideally effective.

They hoped to define components of a model toward which medical teams and health care organizations could strive. They noted that the term “integrated” may imply a one-time service that is completed rather than ongoing, and that such programs are more inclined to emphasize healing, wellness, and the entire patient than conventional services. Therefore the term “integrative health care” would be more appropriate than “integrative medicine.” They noted that while integrative health care was of increasing interest among patients, HMOs, regulatory bodies (nursing, medicine, and pharmacy), health policy makers, and providers who found such caregiving more satisfying, few academic programs were offering courses on integrating health care services.¹

The actual dovetailing of services (providing several disciplines’ services on the same visit) benefits pain patients and providers in terms of satisfaction, treatment outcomes, and eventual health care costs. For this reason, I make every attempt to link my patients’ visits to their appointments with other hospital providers. Coordinated visits are beneficial because

- (1) Like patients in primary care, patients often have transportation constraints or find it prohibitive to return for an office visit with a mental health provider. The more disabled the chronic pain patient

1. As mentioned above, many patients come to primary care clinics with mental health needs that are the result of (or lead to) a physical illness or pain exacerbation. Growing awareness of this and the demand for more efficient hospital models over the last few years has led to an integrated care model in primary medicine fields. In Vogel, Kirkpatrick, and Fimiani’s (2008) integrated health care model, psychologists work as members of a fully coordinated medical treatment team in shared clinic space, as we do at the University of North Carolina Pain Clinic. This provides better care to patients and leads to improved patient satisfaction and more job satisfaction for physicians and saves physician time, which is cost effective for the facility. Integrated health care is said to be the preferred model. Two other models, the co-location model, in which psychologists and physicians work in proximity to one another to facilitate referral, and the consultant model, wherein the psychologist evaluates patients and shares information with physicians, do not allow for the integrated treatment described above (Elder, 2008). The barriers to integrated health care practice, all of which are relatively easy to surmount, include lack of training on the part of physicians and psychologists, rapid turnover of providers in a teaching hospital, and difficulty setting up the billing mechanism. The demand for integrated health care providers has led universities to go beyond their already existing healthy psychology courses and degrees to offer PhD and postdoctoral programs that teach psychologists to work in integrated health care. Clinical conditions commonly treated include substance use and abuse, health-compromising behaviors, pain, GI, sleep mood and stress disorders, somatization, grief, and crisis management (see Smith & Crockett, 2008)—all of which present in a pain clinic on a daily basis. In addition, many integrated health care psychologists are prepared to see inpatients on a consulting basis and to train physicians in the behavioral aspects of disease and symptom presentation.

is, the greater his or her ambulation, driving, and financial constraints are likely to be.

- (2) Patients and their families often see mental health care as unrelated to pain until they learn differently from treatment experience. Patients often fear that if doctors see emotional factors as contributing to the pain, they will no longer take the pain seriously. In short, some patients refuse to see a psychologist unless it is programmed into their clinic visit. Research shows this to work best when the patient perceives a good working relationship between the providers, and when the work they do is billed as related to pain and physical well-being rather than mental health.
- (3) Opioid use factors into psychology appointment scheduling in a number of ways: (1) patients do come to get their opioid prescriptions filled, but they are less likely than most to honor appointments not involving opioid prescriptions, and (2) patients who overuse medication and are in jeopardy of being terminated as clinic patients need comprehensive management for addiction and noncompliance.
- (4) The psychological interview can identify behavioral or emotional aspects of the pain or medicine regimen that could otherwise be missed, and combined appointments give the physician access to that information immediately. Realistically, it is difficult for providers to contact one another or read e-mails about patients in a timely manner. We regularly meet in the hallway to exchange information.
- (5) Patients may not tolerate procedures well without psychological preparation, which can be done on the same day.
- (6) Patients may be willing to tell the psychologist, but not the physician, that they have not been or are not going to comply with their prescribed medication regimens.
- (7) Antidepressants, anxiolytics, and sleep medication may be in order, or there may be psychological side effects to pain medication, such that prescription writing may warrant teamwork.
- (8) Residents and medical students can see the interdisciplinary treatment of pain in action. They see how the team interacts with other hospital and community clinics and providers in the care of their mutual patients.
- (9) The physician may not know he or she needs to consult with the psychologist until the patient is actually in the clinic. New patients may turn out to be complicated and returning patients may have encountered adverse life events since their last visit or may disclose suicidal thoughts or plans. This will be illustrated in the clinical examples presented below.

- (10) Comprehensive treatment can teach patients to see pain holistically and to be proactive. A good way to get patients on their own treatment team may be to offer them the opportunity. A well-known pain physician/psychologist routinely screened his patients with five questions: “Do you want to get rid of the pain?” “Do you want to get rid of the pain?” “Do you want to get rid of the pain?” “Would you be content to be rid of half the pain?” and—most significant—“Are you willing to be the agent to getting rid of the pain?” (Dubin, 1995).
- (11) Interdisciplinary providers who talk together have patients who feel well cared for and heard. Research shows that patients are more content with health care providers who evaluate the treatment they are giving them, and peer review counts toward that. In the end, our patients market our services for us.
- (12) It can be grievous over time for medical and mental health providers to work with patients who are suffering and cannot get well, but it is easier when the treatment environment is compassionate, and when there is mutual support among providers. Physicians do report appreciating the presence of a psychologist teammate in their clinics.

Providing continuous behavioral medicine care can be challenging in when physicians rotate through the clinic on varying weekdays and when the rate of walk-in visits is high. Coordinating schedules requires extra time, personal flexibility, and commitment to providing the service. The solution is for the psychologist to be on-site and have a flexible appointment template to fit around the schedules of the physicians, who coordinate their schedule with nurses, X-ray equipment, and the like, and who undoubtedly are the primary revenue generators.

COMPREHENSIVE PSYCHOLOGICAL TREATMENT IN THE PAIN PRACTICE

The Pain Psychologist

The Accreditation Council of Graduate Medical Education understands that clinics differ and encourages them to train fellows and practice chronic pain behavioral medicine according to the strengths and staffing of their institutions. My particular background includes public health, community psychology, child abuse and trauma, Ericksonian hypnotherapy, consultation/liaison work, and personal coaching. Noisy or hectic hospital

settings with frequent interruptions and scheduling changes, a fast-paced schedule, and multiple agendas necessitate multitasking in the clinic and amendments to usual treatment protocols. Psychotherapeutic tools should include brief therapy, hypnotherapy, CBT, insight therapy, patient education, career counseling, and addiction counseling, with attention to suffering and a positive mind-set. I coordinate with community mental health care providers wherever possible. Again, other clinics have different models.

In most academic hospitals, psychologists with PhDs independently bill for services and teach in residency and fellowship programs; as their salaries are usually lower than physicians', they generate less revenue but are also less of a financial risk to the institution. Medical departments' billing systems need to be set up with a procedure and diagnostic codes and methods of securing authorizations for treatment, without which the psychologist's services are not cost effective. A clinic coordinator who is knowledgeable about multidisciplinary billing, authorizations, and patient flow is invaluable and may make or break the collaboration.

The Pain Psychology Office

Offering pain therapy in the setting where the pain is medically treated helps the patient understand the connections among the emotional, behavioral, and physical aspects of his or her problems; it also takes away the stigma of seeing a “shrink,” who now is labeled a pain practitioner. Sessions in the office are a “timeout in space,” a sort of sacred space in the clinic. Our psychology office was carefully designed to feel comfortable, emotionally safe, and inviting in a way that promotes relaxation. The office contains healing stones, aromas, and soothing tapes to make the therapy experience richer. There is also a lending library of books and other educational materials. The office door is soundproof to prevent distractions and ensure confidentiality. Located in the clinic near the physicians' workroom, curbside consultation is relatively easy, and it is clear to patients that we are interdisciplinary.

BEHAVIORAL MEDICINE SERVICES

Treating Preexisting or Concurrent Pain-Related Trauma

Any traumatic event can exacerbate a chronic pain. When patients come to clinic with a sudden increase in pain, a psychologist can often help them identify and

resolve the triggering event and use it as an opportunity to teach them how to keep their bodies calm in the wake of trouble. This was important in the case of a 28-year-old new mother with Crohn's disease. She had been in remission for some years but had an exacerbation that led to surgery when her newborn son was diagnosed with a life-threatening disorder that required 24-hour monitoring. Therapy for pain, stress, and life management helped her handle stress, grieving, and reality; she learned to relax her body so that her surgical wounds could heal.

As mentioned before, a high percentage of chronic pain patients have histories of trauma and/or PTSD. They may have worked through the trauma successfully only to have chronic pain trigger their sense of vulnerability and powerlessness, which can exacerbate their pain. For example, a 54-year-old female patient was managing chronic pain, poverty, and the loss of her husband fairly well until she lost three more family members to murder. She then experienced a severe bout of a painful skin disorder. Unable to drive in that condition, she requested a phone consultation with the psychologist.

The following patients saw a pain physician rarely but saw the pain psychologist regularly for treatment.

- (1) A 38-year-old was referred to the psychologist when he developed incapacitating chest pain. He had left his long-time job to become a fireman after 9/11 but soon after suffered two heart attacks. A shunt procedure left him with a muscle spasm near the heart that hurt and frightened him daily. His body was so tense it seemed to reverberate with every word he spoke. In reviewing his life events, we identified earlier sources of his anxiety and tension even before the heart attacks had become a way of life. Up to then, his refuge from stress had been work. Now that he was disabled, he feared death, had lost his life purpose, and had forgotten how to relax. During therapy sessions we used a CD of shaman drum music that matches the natural harmonies of the brain; he learned self-hypnosis for pain and anxiety management and completed treatment in 6 sessions.
- (2) A 47-year-old male patient was referred to the psychologist because his edgy and anxious behavior frightened the staff. He had active Crohn's disease, a violent temper, a tumultuous marriage, sleep problems related to PTSD, a long-standing social anxiety disorder, and pain from surgeries at multiple sites. We coordinated his visits with his gastroenterology appointments and addressed symptoms of PTSD

from war and physical child abuse. When he had better control of his behavior, he was referred to a pain physician for epidural injections and opioid medication.

- (3) A 52-year-old female was referred for CRPS-related foot pain after an injury. A high-functioning professional, she also had diabetes, high cholesterol, asthma, allergies, high blood pressure, irritable bowel syndrome, and fragile bones. We addressed family and sexual dysfunction, relationship problems with others, and development of a healthier lifestyle, interlaced with psychotherapy specific to her history of child sexual abuse. She came weekly at first and then less frequently over 3 years, during which she discontinued her blood pressure, cholesterol, allergy, and asthma medications; attain normal weighted; and learned to control her diabetes through her diet. Astoundingly, a subsequent bone density test showed normal bone density in the foot with CRPS. Medications and procedures alone could not get her there, making therapy both cost and time effective.
- (4) Pain is sometimes a body memory that marks the spot where there is unfinished social or emotional business. A 38-year-old professional presented with shoulder pain and numbness in his dominant arm. Therapy revealed that he felt powerless in regard to helping his father, who had dementia, and in his desire to leave his lucrative profession. Once the mind-body connection was identified, he began to work on these life issues and his pain and weakness went away. Another patient presented with shoulder pain that originated after a battle wound, but there was no diagnosis to explain the pain symptoms and location. He also demonstrated extraordinary pain tolerance and there were hints of dissociation in his presentation. Underneath the battle wound was the buried memory of physical child abuse, which had resulted in two previous injuries to that arm. He processed this in therapy, and medical management of the pain was no longer necessary.

Finally, patients who fear needles or who have had traumatic experiences with injections, invasive procedures, or surgeries may look upon them with trepidation. A psychologist can treat fear of needles; psychologically prepare the patient for steroid injections, nerve blocks, or other procedures; or even use hypnosis or relaxation techniques in the procedure room to help the patient through it. This is a billable outpatient service that facilitates an important and lucrative medical one.

PSYCHOLOGICAL TESTING

Many practitioners find that assessment tools are an efficient way to get to know pain patients. Such tools can indicate what issues may hamper pain management treatment and also help predict the success of certain medical treatments. Standardized tools for assessment of pain include the Symptom Checklist 90–revised (Derogatis, 1994), a self-report measure assessing factors such as somatization, obsessive-compulsiveness, interpersonal sensitivity, mood, paranoia, and psychosis. The West Haven–Yale Multidimensional Pain Inventory (Kerns, Turk, & Rudy, 1985) measures patients' self-reported responses to their pain, their activities of daily living, and their significant others' reactions to their pain. The Millon Behavioral Medicine Diagnostic (Millon, Antoni, Millon, & Davis, 2003) assesses psychiatric states that interfere with pain coping, specific coping styles, lifestyle and daily habits, and other psychosocial variables. The Beck Depression Inventory (Beck, Brown, & Steer, 1996) is a quick and efficient way to assess mood.

SCREENING FOR USE OF MORPHINE PUMPS AND SPINAL CORD STIMULATORS

Implanting morphine pumps or SCSs is often last a resort for pain management. As there is surgical risk putting them in and removing them, the stakes are rather high when appropriate patient candidates are chosen. Third-party providers usually require a psychological or psychiatric evaluation before they will reimburse SCS or pump placement, as research shows less success with pain relief in patients with psychopathology or mood disorders. Panic and conversion disorders in patients who receive pumps or stimulators can result in complications or wasted effort (Sheu, Gollog, Esteban, Podder, & Cruciani, 2006). As easy as it may seem to coordinate evaluations and care with mental health providers out in the community, communication with off-site clinicians is not immediate, and reports may not directly address the physician's exact question. Another advantage to having the screening done in the clinic is that a patient who does not pass the screening may get therapy and receive the implantation later. Also, since pain doctors often acquire SCS and pump patients for the long term, while the patients are becoming eligible for the implant, providers have the added opportunity to find out how well they will fit into the practice long term.

A 32-year-old woman came for an SCS screening with a diagnosis of bipolar disorder and a substance abuse history. She had low back pain and pain in one foot shooting up her leg, and her hands hurt. On the first visit, she disclosed a history of incest, a recent divorce, and an enmeshed family situation wherein she and her abusive brother, who was an active substance abuser, were still dependent upon their parents; both siblings had substance abuse histories. In treatment, we addressed the psychosomatic aspects of the hand and foot pain. As we worked through her history of incest and the substance abuse stemming from it, I worked with her local physician and psychiatrist to arrange for ECT for depression and pain. Her hand pain and some leg pain resolved with the ECT, and then her pain physician continued to explore the organic back pain. She did not, after all, receive a stimulator, but she did learn to differentiate pain from misery and resolved some family issues. The case points out some of the complexities of pain: that (1) emotions are felt first in the body, (2) there are body memories of pain that are stronger and longer lasting than cognitive memories, (3) every posture is a figure of body language speech from the unconscious mind, and (4) metaphors referring to physical actions or the body have primitive roots but describe timely physiological connections.

Another advantage to in-house screening for implantable devices is that when occasional complications arise, such as a surgical mishap or a perioperative inpatient crisis, there is someone on hand who knows the patient well. Both can occur (and have), and in some cases the psychologist can, with sensitive patient care, avoid the unnecessary hospital patient relations crisis or legal action. Also, recently, a 50-year-old female in the midst of an SCS trial lost her job of 29 years. In her shock, her pain exacerbated and she asked to discontinue the trial, which was otherwise successful. I was able to see her immediately to resolve the exacerbation and handle her distress.

PAIN MEDICATION MANAGEMENT, SUBSTANCE ABUSE, AND ADDICTION

As depression, anxiety, and chronic pain work cyclically, potentially causing and increasing one another, and as the perception of pain is so closely linked with emotions, most chronic pain patients are on psychotropic medications at one time or another. Interestingly, most medications to relieve pain, other than non-steroidal anti-inflammatory drugs, are psychotropic in nature. The psychologist may suggest such medications to the

prescribing physician and can alert the physician about subsequent side effects, compliance, improvement, and medication abuse.

Pain patients' need for opioids is complex; screening for substance abuse potential is beneficial to keeping order in the clinic and to helping patients get good care. Research shows that a history of substance abuse leaves one vulnerable to opioid medication overuse in the future, and so might destitution itself (Salsitz, 2004). They can also lead to poor self-care and poor compliance with medication regimens. The psychologist can (1) assess patients' likelihood of substance abuse, (2) help patients with compliance, (3) refer patients who inadvertently become substance abusers for concurrent treatment, (4) identify those patients who may need high doses of opioids due to their personal biochemistry or their trauma backgrounds, and (5) help decide when and how to terminate noncompliant patients. Our hospital has an alcohol and substance abuse treatment program (ASAP), where patients can receive individual and group counseling. The clinic's working relationship with the ASAP allows patients to attend that program and still maintain their status in the pain clinic. Otherwise, patients are referred to local mental health or methadone clinics.

There are some measures designed to assess risk for opioid medication misuse among chronic pain patients, such as the Pain Medication Questionnaire (Holmes, Gatchel, Adams, Stowell, Hatten, Noe, & Lou, 2006) and the Current Opioid Misuse Measure for patients on long-term opioid therapy (Butler, Budman, Fernandez, Houle, Benoit, Katz, & Jamison, 2007). All patients prescribed opioids should be educated on addiction, pseudo addiction (drug seeking for pain relief rather than reasons of addiction), tolerance, dependency, and withdrawal symptoms. The psychologist can help the physician differentiate addictive, pseudo-addictive, and tolerance behaviors from one another.

One addiction is often an indicator of others, and they are often difficult for physicians to discover during clinic visits. A 46-year-old former alcoholic with chronic pancreatitis was being considered for a morphine pump; she was at risk of medication misuse. Her pain bouts appeared to trigger panic, which would result in a cycle of vomiting and wrenching that worsened the entire condition and led to multiple ER visits for pain medication. One day she presented to clinic vomiting and in pain. We used mild hypnosis and IV phenergan, which effectively resolved the problem. She subsequently underwent psychotherapy for anxiety, learning breathing and relaxation techniques as an antidote to the cycle, and she was prescribed anxiety medication to use at

the earliest onset of pain. When she subsequently "borrowed" street drugs, she was referred to a local substance abuse clinic for group treatment and toxicology screens. She now attends a treatment program. This was a complicated patient for us to manage, but doing so reduced overall health care costs and resulted in her getting the right care.

LIFESTYLE CHANGES AND ADJUSTMENTS AND OVERALL HEALTH CONCERNS

We address lifestyle changes that commonly accompany chronic pain, including loss of social contacts, poor sleep, lost sense of purpose, and reduced exercise and outdoor time. Sometimes lifestyle plays a very large part in (1) how patients became ill or injured in the first place, (2) why they don't heal, (3) why they are miserable or suffering, or (4) why their immune systems are compromised. Preexisting habits that could make things worse or that work against healing include heavy smoking, food addictions, and even certain exercise patterns. The ideal clinic might include a smoking cessation program offering ongoing support and a stricter policy for nicotine abstinence. Again, pain is an interpretation of and response to a physiological signal and the suffering is optional. Recent research shows the positive effect on the body of feelings such as hope, gratefulness, and forgiveness, so positive attitude is always addressed.

Medical treatment itself sometimes leads to problems. Pain medications, particularly opioids, can complicate life even more, with, for example, bowel dysfunction, changes in sexual functioning, memory loss, and cognitive impairment. Also, patients vary in their willingness and ability to comply with standard prescribed treatments, and they fare best with a little coaching or monitoring or an individualized plan so that they have reachable goals that correspond to their interests, strengths, and current condition.

ALTERNATIVE MEDICINE REFERRALS

To go beyond the work I do with patients on self-care, I keep a list of alternative medicine practitioners who work well with consulting providers, including physical therapists (water therapy, Feldenkrais method, cranial sacral therapy, and myofascial release); chiropractors; acupuncturists; and energy therapy, Reiki or healing touch, and massage practitioners. Such a list can make

the difference as to whether patients actually call such practitioners and whether they have success. With patients who live outside the local area, we often get on the computer together to find practitioners. Please note that it is both wise and courteous to check with the treating surgeon or pain physician beforehand.

HYPNOSIS TO TREAT THE PAIN

Integrating hypnosis into other disciplines, including pain management, is the subject of another chapter in this book. Hypnosis actually began in medical practice as a way to improve mortality of surgical patients before anesthetics and analgesics were perfected, and it has been used for many years to help patients alter, modify, diagnose, and alleviate pain; increase it; or forget to notice it. Hypnotherapy is relaxing and comforting and can simultaneously change the cognitive and physiological responses to nociception (alleviate pain), promote healing, and introduce strategies to manage future pain better, all with the same cost-effective application. For a detailed description and review of hypnosis for pain management, see Hernandez (2010).

PREPARATION FOR SURGERY

Wherever there is surgery, there is likely to be pain. Numerous studies have shown that patients who are relaxed, ready, informed, and in a positive frame of mind regarding their upcoming surgery do better than those who are not (see Devine, 1992; Johnston & Voegelé, 1993). Stress itself has an impact on wound healing (Kiecolt-Glaser, Marucha, MacCallum, & Glaser, 1998), but stress can be minimized when the patient understands the procedure and course of healing, and when he or she resolves worries that he or she and the surgeon may not have discussed. Perioperative psychological preparation is cost effective for patients and their hospitals, as it often leads to decreased need for pain medication, shorter inpatient stays, and fewer surgical complications, including less blood loss (Montgomery et al., 2007). Comfort level with surgery may be most important in the case of abdominal, genital area, head, or neck surgery, as we know that even under general anesthesia, at some unconscious level the patient is aware of what goes on in the surgical suite. Deardorff and Reeves (1997) recommend a detailed initial assessment of the patient and describe a CBT approach to prepare patients for surgery. Hypnotic preparation (see Kessler, Kessler, & Dane, 1996) has the advantage of targeting

the surgeon-specific and surgery-specific experiences, and reframing them positively at the unconscious level. Hypnosis also successfully targets pre- and postoperative anxiety, blood pressure, patients' sense of control over their feelings (Hart, 1980), pain, nausea, vomiting, blood loss, both objective and subjective wound healing (Gurgevich, 2003), hospital stays, and pain medication use (Lobe, 2006). In selected cases, hypnosis may be the only anesthesia. Kessler et al. (1996) highlight the need to dispel patients' expectation of negative surgical outcomes that come from previous negative experiences of either the patient or those close to him or her. A combination of both CBT and conversational hypnosis may be most cost effective (Kessler, Dane, & Galper, 2002), and this may be conveniently done in the pain or surgery clinic.

BIOFEEDBACK TO TREAT THE PAIN

Biofeedback provides the patient with real-time feedback about physiological mechanisms related to their pain that are within their control. Biofeedback machinery most commonly measures muscle tension, blood flow, brain waves, and heart rate. Some psychologists are biofeedback technicians and effectively combine the two services. Chronic pain is always a psychological event, and when one learns to release the pain, thoughts, emotions, and even flashbacks may surface. Unfortunately, there are reimbursement issues with biofeedback, and only certain diagnostic codes and certain types of pain are covered by the major insurance carriers. Yet in addition to providing pain relief, it has no side effects and teaches the patient to heal his or her own pain.

CURBSIDE SERVICES TO OTHER MEDICAL PROVIDERS

Our pain clinic is housed in a treatment center that houses neurosurgeons, orthopedic surgeons, physical medicine and rehabilitation doctors, and physical therapists so that we may work in a multidisciplinary fashion, making referrals and consultations to one another. The center shares staff, and often the psychologist as well. The physical therapist also sees a wide variety of patients and occasionally encounters one who would benefit from counseling, health coaching, or therapy, such as a 45-year-old woman he referred to me for help with anger management. Her anger seemed to exacerbate her neck and shoulder pain, and work issues

exacerbated shoulder tension and impeded healing of her neck injury. Therapy allowed her to work through buried memories triggered by the pain she experienced while working, including a near-death experience from early childhood that involved neck pain. The surgeons also call on psychologists for various reasons. Research shows that surgical outcome improves when patients are surgically prescreened for psychosocial problems and health-compromising behaviors. Some patients need assistance coping with failed surgeries and others encounter addiction problems from pain medicine. One surgical candidate was found to have a cocaine addiction that needed resolution before surgery (anesthesia) would be safe. The psychologist counseled her and then referred her to the ASAP.

OCCASIONAL DAMAGE CONTROL

Psychologists are sometimes more effective at quelling violent behavior and resolving disagreements than security guards, and calming slightly agitated patients clears the path for physicians to spend their time on medical issues. While such seemingly primitive outbursts occur in any clinic, they often bespeak the helplessness and despair that chronic pain patients can feel. For example, a 50-year-old male patient had a miscommunication with his physician and ran out of the clinic, exhibiting bizarre and frightening behavior in the waiting room. He himself asked to see the psychologist and calmed down when he put his distress into words. Chronic pain patients who express suicidal thoughts are always assessed before they leave the clinic. This is usually cost and time effective, and kinder than sending them to the crisis service or to the ER, voluntarily or involuntarily.

INPATIENT PAIN CONSULTATION

On any given day, there are inpatients whose healing is impeded by distress that manifests as pain. They often need help adjusting to their disease or healing process or they are traumatized by the events that brought them to the hospital. These patients do not fall under the scope of a psychiatry consult service, the primary function of which is to evaluate psychiatric status and recommend psychotropic medication, or of the social workers, who plan for outpatient care. For example, a 30-year-old mother with Crohn's disease was taking an excessive amount of pain medication and refused to go home even though she was ready for discharge. She disclosed to me that she no longer loved her husband and

was unwilling to go live with her parents, who were poised to care of her and her son; this was a psychological issue, not a medical one. This patient was on a surgery ward, where physicians are less accustomed to addressing such mental health issues, and where the consultation was that much more welcome.

CHRONIC PAIN THERAPY GROUPS

Research shows therapy and educational groups to be a time- and cost-effective route to pain management. The format is usually 6–12 sessions and teaches pain management skills such as relaxation, self-hypnosis, maintaining a positive attitude, and talking to the family about pain; sometimes the groups include the spouses. Most pain management groups use CBT, but Brown and Fromme (1987) and Spira and Spiegel (1992) describe successful hypnotherapy models. Keefe, Beaupre, and Gil's (1996) group model includes training in coping skills, relaxation, self-pacing of physical activity, and relapse prevention. LeFort et al. (1998) provided 6 sessions addressing exercise, depression, nutrition, and problem solving, with time for interchanges with other chronic pain patients. Groups vary according to the amount of education, psychotherapy, and social support they provide. Rehabilitation programs are often in-house or run from 9 am to 5 pm for 3–6 weeks. Psychological pain management tools and other topics discussed in this article are interspersed through treatment programs, which may include physical and occupational therapy and career skills.

Outpatient groups are much best utilized when patients live near the facility, as travel is often painful and expensive for disabled patients. If attendance is low or unpredictable, individual sessions can be offered following the same format. We designed a 6-session program for spine patients that included back care and information about physical therapy, and a 10-session self-hypnosis program for chronic pain patients.

APPLICATIONS AND CASE STUDIES

The purpose of this chapter is to describe interdisciplinary pain medicine and the role of psychology in chronic pain management. To demonstrate what a pain psychologist in a state hospital may do on a daily basis, the following section outlines the clinical care I gave to chronic pain patients on the day before and the day after I began this chapter. In all, I saw 12 patients in conjunction with their other providers, and 3 others

who are clinic patients but did not see their physicians that day.

- (1) A 45-year-old man is being screened for an SCS. He is also being tapered off high doses of opioid medication prescribed by other providers and is being treated for obsessive-compulsive disorder and depression. He is monitored for low testosterone and is offered regular psychotherapy for lifestyle management. Depression triggers the desire to be active, but activity triggers pain and anxiety. He is currently learning self-hypnosis to manage both pain and mood swings. There is ongoing communication among his providers.
- (2) A 52-year-old active military woman who has had two spine surgeries here in the past 2 years was referred for treatment of depression. She still has disabling arm and hand pain and an immune system disorder. She is depressed about the outcome of her surgeries and is benefiting from counseling, support through her retirement process, and case management, as she sees many providers.
- (3) A 76-year-old woman who presented with chronic arm pain after a routine allergy shot was referred for psychological pain management, with suspicion of somatization. She actually has nerve damage. She also suffered the loss of a child and many other traumas in her life for which she has never been treated. I have seen her monthly since she came to clinic 5 years ago. I referred her to the ear, nose and throat specialist regarding dizziness, which was the first symptom of a brain tumor, and managed her care with the physicians who treated the injuries from two falls, her allergies, and interstitial cystitis. Obviously, she experienced many lifestyle changes through these years.
- (4) A 45-year-old woman initially sought help managing work responsibilities in the wake of chronic back pain, but since that time she has suffered a 1-time addiction to oxycontin; a hysterectomy, which led to major depression; and narcolepsy due to high doses of pain and psychotropic medications. She has done very well with combined psychotherapy and pain management and is happy with her family life and the adjustments she has made. She is currently on a weight loss program.
- (5) A 60-year-old walk-in patient has back pain, diabetes, and high blood pressure and is morbidly obese. She has had a negative outcome from surgery and is considering a lawsuit. We are working on improving her relationship with her surgeon, her health-compromising behaviors, and her depression. She is intellectually challenged, which hampers her communications with providers and her compliance with treatment.
- (6) A 45-year-old woman was referred by another clinic when she disclosed that she has been dangerously abusing her pain medication and asked for help. I arranged a medical consultation regarding her withdrawal symptoms and pain medications and arranged care through ASAP. This eventually resulted in an inpatient stay and continuing substance abuse support, as well as some marriage therapy regarding family adjustment to her pain and her husband's addictions.
- (7) A 45-year-old woman is brought down the hall by her spine surgeon. She was under consideration either for surgery or for an SCS for her back pain, but on this day she is very distraught. During the visit she disclosed a distressing family disagreement, her son's cancer diagnosis, and feelings of vulnerability due to the pain.
- (8) A 50-year-old highly functional woman was originally referred by the physical therapist, who was concerned about the patient's adjustment to her medical condition and her noncompliance with her exercise program. Since then she has been working through a history of physical child abuse and adult emotional abuse and has made many lifestyle modifications to improve her productivity and overall well-being.
- (9) A 40-year-old woman now working in another state began seeing me while on disability for 2 years with back pain and an anxiety disorder. During that time we addressed the sources of the anxiety and worked through some family stressors, and she had an SCS implanted. This visit is a physical and mental health checkup. We are all proud of her recovery and the hard work she has done with us.
- (10) A 45-year-old man who is an engineer with an anxiety disorder and phantom limb pain has lived with his parents under highly stressful conditions for several years. A former substance abuser, he was referred for pain management while he was an inpatient healing from bedsores. He is highly motivated because he is aware of both the effect of his anxiety on his pain and his inappropriate desire for opioid medication.
- (11) A 48-year-old man is a long-standing clinic patient with back pain and depression subsequent to treatment for alcohol abuse. He failed two urine toxicology screens and eventually admitted to substance abuse. He remained in treatment with ASAP and

with me until he regained the clinic's trust that he would no longer abuse medications. He appreciates his checkup with me every few months.

- (12) A 21-year-old college student has debilitating low back pain that eludes clear diagnosis. He has a complicating immune disorder acquired abroad, and a strong desire to achieve more than he can with chronic pain. He cannot sit long enough to attend class, and his social activity is curtailed. We have addressed many lifestyle issues and have facilitated referrals through the medical system. He has learned self-hypnosis for pain management and anxiety control. Although his physical condition remains unchanged, he is doing better socially and is now poised to graduate and take a full-time job.
- (13) A 50-year-old woman's pain physician brought her down the hall when he discovered that she was 2 months short of her pain medication supply. She is on disability for anxiety and neck pain. She became distraught and told him that she had a suicide plan. She and I discussed the many ongoing family crises of late, including her child's substance abuse and theft of her medication, and her physician and I developed a care management plan.
- (14) A pain physician brought a 56-year-old patient down the hall; she was distraught, complained of an inability to eat due to nausea, and had used up her supply of pain pills due to consistent vomiting. Formerly a substance abuser, she is grieving the recent loss of both parents and has ulcer disease. There were several issues to address on this visit, but she was able to quell her anxiety and drink a milkshake with me before leaving the hospital.
- (15) A 25-year-old patient was referred to me by the Employment Security Commission for evaluation and subsequent treatment. He was originally denied medical care for neck and back pain and subsequently suffered spinal cord damage and depression. I have managed his care for injury-related illness and pain. He is responsive to psychological pain management and therapy, is rebuilding his trust in the medical system, and has started a home business appropriate for his medical condition.

PAIN PSYCHOLOGY NETWORKS

Finding Training and Finding Patients

Psychology postdoctoral training in pain management is available for psychologists through pain clinics across

the country and can be found in the APA's monthly *Monitor* employment advertisements. The American Society of Clinical Hypnosis and the Society of Clinical and Experimental Hypnosis are two professional organizations devoted to training and perfecting the practice of hypnosis in medicine. There are regional weekend workshops offered around the country, and the annual meetings offer numerous workshops on pain management for beginning and advanced students. Pain psychology is not currently a division of the APA and there are no board exams specific to the discipline.

Psychologists who are not in a hospital setting often advertise their specialty in the treatment of pain through the media, or they work with their local surgery, family medicine, or internal medicine practices to get referrals. Some pain clinics have full-time psychologists and others borrow private practice psychologists part-time. On this day, there are 18 positions advertised online; some are postdoctoral positions for psychologists and some are available to social workers and psychiatric nurses as well. All are advertised by multidisciplinary medical practices.

Interdisciplinary medicine not specific to pain is a burgeoning specialty; currently the APA and the National Register of Health Services Providers in Psychology are recognizing the importance of cross-disciplinary care (see numerous articles on this in the 2007 and 2008 issues of the *Monitor* and the *Register*). Pre- and postdoctoral programs are offered at the University of Arizona and at sites mentioned in the *Register*. To be sure, the work will always be challenging and rewarding and the learning curve steep, but psychologists in this role facilitate the success of many on a daily basis.

Quantitative Electroencephalography in the Assessment and Rehabilitation of Traumatic Brain Injury

Kirtley E. Thornton

Dennis P. Carmody

This chapter has two goals: to provide the reader with a general awareness of traumatic brain injury (TBI), mild in particular, and the multiple complex issues involved in this area, and to offer a detailed understanding of the role of quantitative electroencephalography (qEEG) in the assessment and treatment of the cognitive deficits of the TBI patient. Sections I–IV address the first goal. Section I discusses definitions, sports, vulnerable groups, the concept of spontaneous cure, and roles of loss of consciousness and post-traumatic amnesia criteria. Section II addresses the biomechanics of a TBI. Section III discusses the physical damage to the brain caused by the TBI as measured by modern medical imaging. Section IV reviews the neuropsychological and emotional results of a TBI that may be clinically manifested in a patient.

The second goal is addressed in section V, which discusses the scientific basics of qEEG technology, development of the technology over the past two decades, and its application in the assessment of the TBI patient. The coordinated allocation of resources (CAR) model of brain functioning, which employs a cognitive challenge or activation method, is discussed in the context

of how a TBI specifically affects brain and cognitive functioning. An example of the differences between the normative and the TBI response patterns are presented in detail for the cognitive task of auditory memory. We review the results of rehabilitation efforts employing the CAR model, which have proved to be dramatically superior to the minimal results of traditional cognitive rehabilitation models.

SECTION I

Definition, Measurement and Incidence/Prevalence of TBI

TBI is a major medical, social, and financial problem in the United States. The annual cost of 1.5 million cases is \$60 billion dollars. Causes of TBI include motor vehicle accidents, assaults, sports activities, falls, and blast injuries in the Iraq war. The most prevalent type of TBI is mild TBI, which doesn't involve prolonged periods of coma.

Definition of TBI

The Centers for Disease Control and Prevention (2008) defines traumatic brain injury (TBI) as a blow or jolt to the head or a penetrating head injury that disrupts the normal function of the brain, which results in concussion (functional deficits) or contusion (bruising). The blow or jolt can be a direct impact or non-impact event, such as whiplash. The severity of a TBI may range from mild to severe. The signs can be subtle, and symptoms may not appear for days or weeks or may even be missed, as individuals may look fine even though they act or feel differently (Centers for Disease Control and Prevention, 2008). The World Health Organization (1992) codes the injury in the *International Statistical Classification of Diseases and Related Health Problems* as ICD-S06, intracranial injury.

The most prevalent finding of TBI is mild TBI (MTBI), which is estimated to constitute 70%–90% cases of TBI (Torg, 1991). The Centers for Disease Control and Prevention (2008) indicated that MTBI is an injury to the head as a result of blunt trauma or acceleration or deceleration forces that result in either observed or self-reported conditions of confusion, disorientation, memory dysfunction, or loss of consciousness (LOC). Recent definitions of MTBI formulated by the Department of Defense and the Department of Veterans Affairs (Helmick et al., 2006) are consistent with national definitions (Borg et al., 2004; Centers for Disease Control and Prevention, 2003).

The clinical diagnosis and classification of mild TBI are based on several factors, including whether the length of the LOC is less than 30 minutes and whether post-traumatic amnesia (PTA) is greater than 24 hours, in addition to physical and neurological examinations (Borg et al., 2004). As we discuss, the criteria of LOC and PTA present some problems in diagnosis of TBI and are not always useful or clear indicators of possible cognitive effects of a MTBI. The classification of complicated MTBI has been used in cases with neurological deficits that are evident on neuroimaging procedures.

Measurement of TBI Severity

Scales have been developed for use in rapid assessment of TBI, such as the Rancho Los Amigos Scale and the Glasgow Coma Scale (GCS). The better known is the GCS, which is used in emergency departments to evaluate the likelihood of coma and to assess loss of consciousness (Teasdale & Jennett, 1974). It is simple to administer, has a high degree of interobserver reliability (Teasdale, Knill-Jones, & van der Sande, 1978), and correlates well with outcome following severe brain injury (Teasdale &

Jennett, 1976). The GCS provides rating scales for best motor response (obeys commands fully to no response), best verbal response (alert and oriented to no sounds), and best eye opening (spontaneous eye opening to no eye opening) in order to generate a severity score ranging from 3 to 15. Three grades of severity are recognized: severe (8 or less), moderate (9–12), and mild (13–15; Jennett, 2005). Lower scores are associated with poorer functioning. While the GCS is useful in evaluating coma, there are questions about the predictive power of scores that are higher than the cutoff score of 8 for coma. The original studies required that coma be present for at least 6 hours in order to use the GCS score as a tool for assessing outcome (Teasdale & Jennett, 1974, 1976). The scale was not designed to diagnose patients with mild or even moderate TBI, nor was it intended to be used in place of a neurological examination. Instead, the GCS was designed to provide an easy-to-use assessment tool for serial evaluations by relatively inexperienced care providers, and to facilitate communication between care providers on rotating shifts. While single, isolated GCS scores are of limited value, serial scores are more predictive. Some 13% of patients who eventually enter into coma had initial GCS scores of 15 (Jennett et al., 1977). A GCS score of 15 is of no help in determining whether brain injury has occurred.

Critics of the use of the GCS point to problems in diagnosing TBI (Laureys, Piret, & Ledoux, 2005), predicting long-term outcome (Waxman, Sundine, & Young, 1991), and predicting death versus vegetative coma (Braakman, 1992). GCS scores in the mild range (13–14 vs. 15) are not associated with the outcome measures of neurobehavioral symptoms and signs, psychological issues, psychiatric diagnosis, functional and psychosocial outcome, frequency of somatic complaints, or return-to-work rates (McCullagh, Oucherlony, Protzner, Blair, & Feinstein, 2001), despite the fact that the 13–14 group has more CT abnormalities and longer PTA duration. The criteria for MTBI examines the behavior at the time of the event but not the typical symptoms that follow MTBI, which include problems in memory, concentration, and decision making; slowness; headache; fatigability; confusion; mood vacillations; sleep problems; dizziness; balance problems; increased sensitivity to light or sound; changes in vision, smell, taste; nausea; and ringing in the ears (Centers for Disease Control and Prevention, 2003).

Incidence and Prevalence of TBI

TBI is a major cause of death and disability in the United States, with a yearly incidence of 1.5 million; 1.1 million presently live with a disability related to the TBI (Thur-

man, Alverson, Dunn, Guerrero, & Snizek, 1999). As a result of these injuries, 50,000 die, 230,000 are hospitalized and survive, and an estimated 80,000–90,000 experience the onset of long-term disability (Thurman et al., 1999). Table 18.1 indicates the breakdown of the causes of TBI (Centers for Disease Control and Prevention, 2008).

Gender and age are related to the relative risk for TBI. Males are about twice as likely as females to sustain a TBI. The two age groups at highest risk for TBI are infants and children up to 4 years of age and teenagers between the ages of 15 and 19. Adults age 75 years and older have the highest rates of TBI-related hospitalization and death (Centers for Disease Control and Prevention, 2008). Some of the TBI estimates in the literature are based upon emergency room records. However, there is a tendency to underreport, as is evident in one study in which 56% of MTBI patients identified by interview did not have an emergency department record of a MTBI (J. M. Powell, Ferraro, Dikmen, Temkin, & Bell, 2008). Interestingly, the highest emergency department identification occurred when there was a LOC and the lowest when the symptom was confusion. This phenomenon of underreporting casts suspicion on all estimates of MTBI based on emergency department records. The economic impact of MTBI is substantial, accounting for about 44% of the \$56 billion annual cost of TBI in the United States (Thurman, 2001). It is estimated that the cost in the United States in 2000 was \$60 billion, which takes into consideration both the direct medical cost and the indirect cost, such as lost productivity caused by TBI (Finkelstein, Corso, & Miller, 2006).

18.1

Causes of Traumatic Brain Injury

CAUSE	INCIDENCE
Falls	28 %
Motor vehicle accidents	20 %
Struck by/against events	19 %
Assaults	11 %

From *What Is Traumatic Brain Injury?* by Centers for Disease Control and Prevention, 2008. Retrieved from <http://www.cdc.gov/ncipc/tbi/tbi.htm>.

Events Including Sports

The third major cause of TBI is events; this includes sports TBI. Investigators of sports TBI have developed their own body of research literature, including return-to-play criteria. The Centers for Disease Control and Prevention (2008) estimates that there are 1.6–3.8 million sports- and recreation-related concussions in the United States each year.

Breakdown by Sports Activities

TBI in sports is of particular concern given that children and adolescents compete in sports. For example, one report estimates that some 1.25 million athletes compete in contact sports at the high school level (Lovell et al., 2003). Another report examined TBI occurring in 10 sports at 235 high schools and found football accounting for 63% and wrestling for 10% of TBI (J. W. Powell & Barber-Foss, 1999). Data for the years 1985–2000 indicate that ice hockey and rugby had the highest incidence of concussion for high school, college, and amateur athletes (Koh, Cassidy, & Watkinson, 2003). At the recreational level, female taekwondo participants and male boxers had the highest frequency of concussion (Koh & Cassidy, 2004).

However, the estimates of TBI in high school sports are probably on the low side. For example, a survey of high school football players found that only 47% of the athletes reported a concussion at the time of injury (McCrea, Hammeke, Olsen, Leo, & Guskiewicz, 2004). The reasons the students gave for not reporting the concussion were belief that the injury was not serious enough to merit medical attention (66%), desire to stay in the game (41%), failure to recognize the occurrence of a concussion (36%), and desire not to disappoint their teammates (22%).

Criteria for Return to Play

While MTBI is seen frequently in athletes, severity grading and management remain controversial (Gebke, 2002). Evaluation of the concussed athlete is essential before a recommendation to return to play can be made (Putukian, 2006). Often these decisions are made by the certified athletic trainer either on the field or sideline during the game or at post-game follow-up. As such, these decisions frequently do not involve the clinician. While MTBI occurs in athletes of all ages, many injuries are unreported, particularly among recreational athletes. Younger athletes are less likely than collegiate athlete to have access to on-field medical care (Lovell, Collins, Iverson, Johnston, & Bradley, 2004).

Premature return to play exposes athletes to additional risk of more serious brain injury and leads to a worsening of symptoms and lowered threshold for re-injury, as well as the possibility of second impact syndrome. Second impact syndrome is defined as a second injury following incomplete recovery from an initial injury (Lovell et al., 2004) and represents a serious issue as one consequence is death. The decision to return the athlete to play resolves around the identification of a concussion. Concussion is typically associated with grossly normal structural neuroimaging studies. The cornerstone of concussion management is rest until all symptoms resolve, then a graded program of exertion before the athlete returns to sport (McCrory et al., 2005). A research area that has been gaining attention is balance control. The clinician may run across these measures in clinical reports in the future. The Balance Error Scoring System for evaluation of postural instability has been recommended (Guskiewicz, 2001). This balance measure typically resolves in 3–5 days post-injury (McCrea et al., 2003).

An international meeting of professionals involved in TBI resulted in the Prague guidelines (McCrory et al., 2005). One of the guidelines involves a distinction between simple and complex concussions. In the simple concussion diagnosis, the LOC is less than 1 minute and the symptoms resolve within 7–10 days without complications. In the complex concussion diagnosis, there is a prolonged LOC and the symptoms last longer than 7–10 days or there is a history of multiple concussions. The 7-day recovery time frame is consistent with animal research models demonstrating neurometabolic irregularities for 7–10 days after injury (Hovda, Prins, & Becker, 1999).

Other Prague guideline recommendations are that players should not be allowed to return to play in the current game or practice and should not be left alone, and regular monitoring for deterioration of function is essential during the initial few hours after injury. Return to play must follow a medically supervised series of steps involving a graded program of exertion, and players should not return to play while symptoms persist. However, the determination of a concussion is fraught with lack of precision. LOC has proved to be of limited value, however, in return-to-play decisions, as LOC is reported for only 9% of those sustaining a concussion (Guskiewicz, Weaver, Padua, & Garrett, 2000). In addition, the presence and duration of LOC and PTA are not used to differentiate between the symptomatic and asymptomatic sports-related MTBI groups (Collie, Makdissi, Maruff, Bennell, & McCrory, 2006). However, a MTBI group with LOC of 15 minutes

experienced more depression than a severe TBI group (Alexander, 1992). Mental status changes have proved to be useful in return-to-play decisions. Athletes with duration of on-field mental status changes lasting less than 5 minutes demonstrated a return to baseline within 4 days. Athletes with post-injury anterograde amnesia, retrograde amnesia, or disorientation lasting longer than 5 minutes, as a group, did not fully recover in 7 days (Lovell et al., 2003). Resolution of the clinical and cognitive symptoms typically follows a sequential course.

TBI Sequelae in Vulnerable Groups: Pediatric, Repeat Concussions, the Elderly, and Females

When a clinician determines that his or her patient has a history of a TBI, it is important to know more than just the severity of the injury, but also the age, sex, and previous head injury history of the person who experienced the injury. The research reviewed in this section indicates that some individuals are more susceptible to the negative effects of a TBI than others.

Pediatric

Children and adolescent athletes represent a distinct group in that conservative management of concussion is required (Lovell & Fazio, 2008). For example, high school athletes with concussion had prolonged memory dysfunction compared with college athletes with concussion (Field, Collins, Lovell, & Maroon, 2003). Head injuries account for a large portion of school related injuries (Di Scala, Gallagher, & Schneps, 1997). Children with preexisting disabilities are at increased risk of head injury (Limbo, Ramirez, Park, Peek-Asa, & Kraus, 2004; Max et al., 2004), while those with specific pre-existing learning disabilities are more susceptible to the effects of a TBI (Collins et al., 1999).

TBI in children is related to deficits in cognitive functioning, personality (Max et al., 2004), and emotional processing. For example, TBI affects immediate and short-term memory (Catroppa & Anderson, 2002), working memory (Levin et al., 2004; Roncadin, Guger, Archibald, Barnes, & Dennis, 2004), and attention (Catroppa & Anderson, 1999; Goldacre, Abisgold, Yeates, & Seagroatt, 2006). Associations have been found between TBI and diagnoses of attention-deficit/hyperactivity disorder (Max et al., 2004; Scheibel et al., 2007). Intelligence is affected for up to a few years (Ewing-Cobbs, Fletcher, Levin, Francis, Davidson, & Miner, 1997; Ewing-

Cobbs et al., 2006) and attention can be deficient up to 5 years post-injury (Catroppa, Anderson, Morse, Haritou, & Rosenfeld, 2007). In addition, functional deficits in executive function and inhibitory control (Leblanc et al., 2005) last at least 2 years in severe TBI cases (Anderson & Catroppa, 2005; Ewing-Cobbs et al., 1998). Long-term deficits (20 years post-injury) in children with complicated MTBI indicate that children are probably more vulnerable to neuropsychological dysfunction than adults sustaining similar head injuries (Hessen, Nestvold, & Anderson, 2007).

It has also been argued that children “grow into the deficits” as the specific cognitive deficits become apparent years after the injury (Fletcher, Miner, & Ewing-Cobbs, 1987; Middleton, 2001). In section V we will discuss how the phenomenon might be manifested in the qEEG variables. Development of specific long-term learning disabilities is associated with multiple concussions in youth (Iverson, Gaetz, Lovell, & Collins, 2004; Kirkwood, Yeates, & Wilson, 2006). A younger brain may have longer recovery time because of its immaturity (Field et al., 2003). One study indicated that TBI in children results in low self-esteem, loneliness, antisocial behavior, and prolonged memory deficits (Andrews, Rose, & Johnson, 1998).

Repeat Concussions

Some 20% of college football players have two or more concussions during their career (Collins, Lovell, Iverson, Cantu, Maroon, & Field, 2002). A history of previous concussions is associated with decreased memory performance. For example, athletes who had a previous history of three or more concussions were 9 times more likely to demonstrate LOC and greater anterograde and retrograde amnesias (PTA) following a concussion than those without such a history, thus reflecting a lingering vulnerability (Collins & Hawn, 2002; Collins et al., 2002). Athletes with a prior history of concussion were 7 times more likely to show decreased memory performance than matched cohorts (Iverson et al., 2004).

In a study of retired professional athletes with a history of concussions, more than 50% reported experiencing LOC or memory loss from at least one of their concussive episodes (Guskiewicz et al., 2007). Of those with one or two previous concussions, 12% reported that the injuries have had a permanent effect on their thinking and memory skills as they have gotten older. This incidence increased to 31% in retirees with three or more previous concussions, indicating a positive association between a higher number of concussions and the perception that those concussions negatively affect

cognitive functioning. There are studies of the outcomes of TBI in the professional football player showing the association between recurrent sport-related concussion and increased risk of both dementia-related syndromes and clinical depression (Guskiewicz et al., 2007). The dementia related syndromes are probably mediated by the E4 variant of the *ApoE* gene (Emmerling et al., 2000).

The Elderly and Females

The elderly are more negatively affected by TBI, as they show greater decline in the 5-year post-accident period than younger groups (Marquez de la Plata et al., 2008), are more likely to be hospitalized (2.5 times greater than those under 65), have poorer functional outcomes than younger TBI patients (Ashman et al., 2008), and have twice the mortality rates of younger TBI patients (under 64 years) in both mild and moderate TBI cases (Mosenthal et al., 2002).

According to a meta-analytic review of outcome literature, outcomes are worse in women than in men (Farace & Alves, 2000). Female high school and university athletes have significantly greater declines than males in reaction times (simple and complex) within 7 days after their concussion (Broshek, Kaushik, Freeman, Erlanger, Webbe, & Barth, 2005). Furthermore, high school and college female soccer players are 1.2 to 2.5 times more likely to suffer a TBI than male soccer players (Ellemborg, Leclerc, Couture, & Daigle, 2007). In terms of cognitive functions, TBI female athletes demonstrated significantly lower visual memory scores than male athletes (Covassin, Schatz, & Swanik, 2007).

From these research findings, we suggest that the cognitive, personality, and social deficits and problems that are found in these groups may have as their source the TBI, whether the injury was reported or not (Thornton & Carmody, 2005). As such, many psychological interventions that are successful with children without a history of TBI may not be helpful until the TBI deficits in brain functioning have been successfully treated, especially if memory functioning was affected. The problem, however, is that cognitive rehabilitation interventions have not been found to be particularly effective (Thornton & Carmody, 2008). Section V will review the effectiveness of present cognitive rehabilitation models and discuss an intervention that has proved to be particularly effective, the CAR model for EEG bio-feedback. In order to understand the alterations in brain structure and functioning that occur as a result of TBI, in sections III and V we address the neuroimaging and qEEG studies of brain structure and function.

The Invalid Spontaneous Cure Concept

There has been an implicit assumption and sometimes as well as explicit statements in the MTBI field that somehow these brain problems spontaneously resolve or recover over time (Jay, 2000; Wood & McMillan, 2002). What is problematic about this concept is that it is unclear whether the word “recover” implies a spontaneous cure or a compensation. A second assumption is that patients who still report symptoms after a certain period of time are most likely malingering or the symptoms have psychological causes. The concept of resolution implies either a spontaneous cure or a successful compensation by the brain. Despite the research we will present later in this chapter, some reports continue to assert that symptom persistence beyond 3 months after MTBI is psychogenic in nature (Binder, Rohling, & Larabee, 1997; Kashluba, Hanks, Casey, & Millis, 2008). The concept of spontaneous cure is no longer an appropriate, viable, or even a valid concept, and a better model is one that involves compensation, although not necessarily a successful compensation, as some TBI patients live with the cognitive consequences for the rest of their lives.

Initial Estimates

Initially it was thought that 50% of MTBI cases experience recovery by 3 months post-injury, albeit incomplete in some cases (Dikmen, McLean, Temkin, & Wyler, 1986). Other research supports this general time frame in that post-concussive symptoms persisting between 3 and 6 months post-injury occur in about 40% of persons with mild TBI (Ingebrigtsen, Waterloo, Marup-Jensen, Attner, & Romner, 1998; McCullagh et al., 2001). Some reports indicate a range of 1% to 20% of MTBI for long-term negative effects 6 months post-injury (Beetar, Guilmette, & Sparadeo, 1996; Deb, Lyons, Koutzoukis, Ali, & McCarthy, 1999; Leininger, Gramling, Farrell, Kreutzer, & Peck, 1990; Levin & Eisenberg, 1991). Factors that contribute to the long-term effect include a previous history of TBI (Rimel, Giordani, Barth, Boll, & Jane, 1981), alcohol use at the time of accident (Ashman, Schwartz, Cantor, Hibbard, & Gordon, 2004), and female sex (Emerson, Headrick, & Vink, 1993). However, the long-term negative effect estimate of 20% of MTBI has come under increasing challenge by researchers who have indicated that there are symptoms at 6 months, with 50% of their MTBI patients reporting dizziness and headache, and about 75% reporting fatigue (McCullagh et al., 2001).

Estimates from Physical Measurement

Long-term effects have also been documented in physical measurements, such as the protein S-100B serum. The serum S-100B is a peripheral biochemical marker of neural injury, including reactive gliosis, astrocytic death, and/or blood-brain barrier dysfunction (Wong, Rooney, & Bonser, 1999). Associations have been found between MTBI and S-100B (De Kruijk, Leffers, Menheere, Meerhoff, Rutten, & Twijnstra, 2002). Neuropsychological deficits were found in 74% ($N = 36$) of MTBI cases at the 2-week testing point and 67% ($N = 29$) at the 6-month testing point, even though all the patients were fully functional on the Functional Independence Measure in terms of activities of daily living. At 6 months since accident, the MTBI group did not show any signs of intracranial pathology or EEG abnormality (no qEEG data). However, the MTBI group did show significant neuropsychological deficits in the individuals with raised S-100B serum concentrations (about 50% of sample of 79 patients) at 6 months since the accident. In those patients with increased S-100B levels there was a twofold increase in severity of dizziness, headache, and memory problems. All the patients with normal S-100B levels 6 hours after the injury who were not reporting dizziness, nausea, or headaches were fully recovered at the 6-month time period. The S-100B level would indicate that about 50% of the MTBI patients were still experiencing problems 6 months after the accident.

TBI Diagnosis Problems with Use of Loss-of-Consciousness and Post-Traumatic Amnesia Criteria

There are negative and positive arguments for the use of LOC as a diagnostic criterion for TBI. On the positive side, the Prague guidelines (McCrory et al., 2005) make a distinction between simple and complex concussions. In the simple concussion diagnosis, the LOC is less than 1 minute and the symptoms resolve within 7–10 days without complications. It has also been reported that athletes who had a previous history of three concussions were 9.3 times more likely to demonstrate LOC and greater anterograde and retrograde amnesias following a concussion than those without such a history (Collins & Hawn, 2002; Collins et al., 2002), reflecting a lingering vulnerability. A MTBI group (LOC 15 min) experienced a significantly higher proportion of cases

involving depression than a severe TBI group (Alexander, 1992).

On the negative side, when the patient comes into the ER there is a tendency for the diagnosis of TBI to be rendered when the patient reports an LOC (J. M. Powell et al., 2008), which may reflect a diagnostic bias. LOC has also proved to be of limited value in return-to-play decisions, as LOC is reported for only 9% of those sustaining a concussion (Guskiewicz et al., 2000). In addition, the presence and duration of LOC do not differentiate between the symptomatic and asymptomatic sports-related MTBI groups (Collie et al., 2006). There are studies of the outcomes of TBI in professional football players showing the association between recurrent sport-related concussion and increased risk of dementia-related syndromes such as Alzheimer's regardless of the presence of LOC (Guskiewicz et al., 2005).

There are also arguments both for and against the usefulness of the PTA criteria for estimating severity. On the pro side, the GCS 13–14 group had more CT abnormalities and longer PTA duration (McCullagh et al., 2001) than the group with a GCS of 15. On the negative side, there was no association between the GCS rating and outcome measures such as return to work, neurobehavioral symptoms, and frequency of somatic complaints. In addition, the presence and duration of PTA did not differentiate between the symptomatic and asymptomatic sports-related MTBI groups (Collie et al., 2006).

SECTION II

The Biomechanics of a TBI

The following description of the biomechanical, biophysical, and biological forces that are produced by a TBI is provided to enable the reader to appreciate the complexity of a TBI. The TBI field was unfortunately hampered initially, and to this day by the use of the term “mild,” which implies a minimal event. The somewhat detailed physical explanations that follow are intended, in part, to provide the reader with an appreciation of the physical dynamics that affect the human brain during a TBI.

There are six distinct biomechanical processes that have been described as likely to be involved in the induction of a concussive (loss of function) state (Shaw, 2002). Table 18.2 shows the processes in the both brain stem effects and non-brain stem effects. We provide a broad overview of the brain's physical properties and the effects of physical forces involved in a TBI on the biology and neuroanatomy of the brain.

18.2

Biomechanical Processes in the Induction of a Concussive State

BRAIN STEM EFFECTS	NON-BRAIN STEM EFFECTS
Hemispheres pivot on base	Impact between brain's surface and skull—shearing/tearing of neurons
Head accelerates with respect to neck	Skull bone is depressed
Acceleration of head about axis of neck	Propagation of intracranial pressure waves
Adapted from “The Neurophysiology of Concussion,” by N. A. Shaw, 2002. <i>Progress in Neurobiology</i> , 67(4), 281–344.	

Brain Neuroanatomy and Anatomy

The human brain weighs about 3 pounds, has a jelly- or gelatin-like quality, and lies within the skull, surrounded by cerebral spinal fluid (5.1 ounces). There are gender differences in the number of neocortical neurons; males (23 billion) have more neurons than females (19 billion) (Pakkenberg & Gundersen, 1997; Pakkenberg et al., 2003). Estimates of the number of synapses in the cerebral cortex are as high as 240 trillion (Koch, 1999). Just beneath the skull resides the cortical gray matter, a thin (.14–.20 inch) layer mainly composed of neurons, glia cells, axons, dendrites, and capillaries. From within the 6 layers of the gray matter the white matter bundles originate and send information to the other parts of the brain. About 5% of myelinated fibers have their origin in the subcortex (the deeper structures in the brain) and connect the two hemispheres, while about 95% of the myelinated axons that are in the cortical white matter are located within the same hemisphere (Braitenberg, 1972, 1978). There are two important structural facts that are relevant to the TBI patient: (1) the white matter fibers reside just beneath the gray matter and the intersection of these two masses provides an opportunity for shearing forces to operate and (2) in the skull behind the eyes and in front of the temporal lobes are sets of jagged boney structures, including such structures as the sphenoid and ethmoid bones. These boney structures are frequent points of impact for the brain.

The brain is composed of two main hemispheres (left/right) each of which has five cortical lobes (frontal,

temporal, sensorimotor, parietal, and occipital). The functions of these lobes can be described very simplistically thusly: the frontal lobe controls executive function, the temporal lobe controls memory and verbal functions, the sensorimotor lobe controls reception of sensory information and execution of motor impulses, the parietal lobe controls association areas, and the occipital lobe controls visual processing. However, these broadly described functions do not do justice to the complexity of the system and multiple interactions involved in any specific cognitive task. This is apparent in the qEEG analysis of auditory memory presented in section V. The cerebellum and subcortical structures are also strongly involved in cognitive function.

Effects of Physical Forces on Biology in TBI

Extensive analyses of the physical forces occurring during a TBI reveal the resultant biological effects. We present a brief overview of these non-brain stem forces and their effects. The classic biological effect of a TBI is diffuse axonal injury (DAI), which was first described by Holbourn (1943) in examination of the mechanical forces of a TBI. His focus was on non-brain stem effects of the impact between the brain's surface and skull (2a), resulting in the shearing or tearing of the neurons; this work helped explain that shear injury is caused by rotational forces and not by linear or translational forces, in which all of an object moves in a straight line in unison.

Acceleration-deceleration forces can produce rotational movements in the brain. Two-thirds of DAI lesions (damaged tissue) occur at the gray-white matter junction, where the density differences are the greatest. The research supports the following magnitude and direction (vector) concepts: "centripetal" force vector, where the pressure is highest at the outer cortex with a gradient to the subcortex and brain stem (Ommaya, Goldsmith, & Thibault, 2002), a rotational vector (Holbourn, 1943, 1945; Lee & Advani, 1970), and a shear vector (Advani, Ommaya, & Yang, 1982; Ommaya, Thibault, & Bandak, 1994). Most injuries occur in the gray matter of the frontal and temporal lobes, independent of the direction of impact to the skull (Ommaya, 1995; Sano, Nakamura, & Hirakawa, 1967). This reflects the additional effect of the brain impacting on the jagged sphenoid and ethmoid bones. The second non-brain stem effect (2b) involves a deformation caused by a depressed skull bone and has not received much attention in the literature. The third non-brain stem effect (2c) is

the percussion shock wave that moves from the impact point and makes contact with the opposite side of the skull in less than 200 ms. The shock wave can result in a "coup contra-coup" injury (Ommaya, 1995; Sano et al., 1967).

A neurochemical cascade involving a multitude of cellular changes develops immediately following the biomechanical trauma to the brain. The biomechanical effects are on the stretching and tearing of the axons. As a result of the physical trauma, edema (fluid) and leakage occur in the axon. This effect is most intense during the first 2 weeks following injury. The resulting lesions (damage) generally involve small areas (.04-.60 inches diameter). Neuronal membranes are negatively affected. The axonal stretching leads to an increase in extracellular potassium, followed by subsequent depolarization and then a release of excitatory neurotransmitters. This has been termed a "neurotransmitter storm" (Mendez, Corbett, Macias, & Laptook, 2005). This sequence involves a loss of ionic gradients, apoptosis (cell death), cell depolarization, cytotoxic edema (swelling of the cell elements), glutamate release, and other biochemical effects. As a result of these events, the neuron breaks down, the axon splits into two sections, a retraction ball (collection of cytoplasm) is formed at the end of the axon, and Wallerian degeneration occurs, which results in axonal collapse and resultant disconnection effects (Povlishock & Katz, 2005).

Non-Brain Stem Neuroanatomical Effects in TBI

When the brain moves sufficiently enough to have an impact with the bone, a contusion (bruising) can occur. The bruising typically affects the superficial gray matter of the inferior, lateral, and anterior aspects of the frontal and temporal lobes. The occipital poles and cerebellum are less involved. A subdural hemorrhage can occur when the movements of the brain are sufficient to tear the bridging veins on the surface. These veins bridge the brain surface to the dural venous sinus. Generally, these subdural hemorrhages are found in parietal and frontal contours. In a whiplash-type injury there is a sudden acceleration and no direct impact. In this situation, the brain's movement lags behind that of the skull. The forces effect the connections between the brain and the bridging veins as well as the brain tissue. Resultant ruptures of the bridging veins can result in subdural hematomas, axonal damage, and bleeding. When the skull stops moving, the brain is thrown against the skull and simultaneously pulls away from the posterior skull. Op-

posite the internal contact a contra-coup can result from the negative pressure, which may cause the formation of cavitation bubbles. The brain is then thrown backwards (deceleration) and a similar dynamic occurs. The reader is referred to Taber, Warden, and Hurley (2006), who illustrate nonpenetrating TBI injury locations for diffuse axonal injury, contusion, and subdural hemorrhages. The illustrations indicate that DAI affects the following locations: the gray matter–white matter (corticomedullary) junction (particularly frontal-temporal), internal capsule, deep gray matter, upper brain stem, and corpus callosum (CC).

SECTION III

Modern Medical Imaging Research with TBI

The past 20 years have seen an enormous growth in the medical diagnostic imaging technology area; these new techniques have been applied to TBI patients. The research has focused on the effects of TBI on cortical structures and functions as well as the differences in the response patterns between a normal group and TBI patients. The imaging techniques vary in their intrusiveness and in the types of information they provide to the clinician. Among the more intrusive techniques that are used for both clinical and research purposes are SPECT (single-photon emission tomography) and PET (positron emission tomography), which require injections of a radiopharmaceutical (SPECT) or radionuclide (PET). The images that are produced reveal the metabolism of the brain (SPECT) or the regional blood flow (PET). The techniques are often combined in clinical applications with other forms of imaging in order to obtain high-resolution anatomic images of brain structures. Computed tomography (CT), also called computed axial tomography (CAT), has been used clinically to reveal brain structure; however, to produce the images, the patient must be exposed to ionizing radiation. A technique that is less intrusive is MRI (magnetic resonance imaging), which uses a powerful magnetic field to produce images of the structure of the brain. MRI requires patients to enter a scanner and remain motionless as the scans are obtained. The advantages of MRI are the lower degree of invasiveness and lack of radiation exposure. A recently developed form of MRI is DTI (diffusion tensor imaging), which is used to visualize the white matter fibers of the brain.

Several techniques for visualizing the function of the brain are available to the clinician. One technique

that requires use of a MRI scanner is functional magnetic resonance imaging (fMRI). Often, for research purposes, the patient's fMRI scans are collected following a structural MRI procedure. The use of fMRI in clinical applications is not common. The fMRI images are used to measure the hemodynamic response of the activity of the brain; one measure of the activity is the BOLD signal, which is the blood oxygen level dependent signal. Typically, the BOLD signal is first measured while the patient is at rest; then the patient is given tasks to perform, with intermittent rest periods. The BOLD signals of the at-rest periods and the task are compared. In this way, the activity of the brain when involved in a task is quantified. It is possible to look at the activity of individual patients and also to combine the activity of groups of patients to identify brain regions involved in tasks. Such tasks might involve attention, memory, and problem solving, which are the processes that are affected by a TBI. While brain function attributed to a task is determined by comparison to function at rest, there are concerns that brain regions active in the resting state are, at times, more active and are active in different ways than when involved in cognitive tasks (Gusnard, Akbudak, Shulman, & Raichle, 2001; Gusnard & Raichle, 2001; Raichle et al., 2001). To manage this concern, some fMRI studies have used a different comparison to identify differential brain function. For example, one study examined the patient's brain activation after hearing his or her own first name in contrast to hearing the names of others (Carmody & Lewis, 2006).

There are techniques that are less invasive than SPECT, PET, CT, and MRI. They measure the electrical activity of the brain, rather than metabolic or hemodynamic processes. These techniques include EEG, ERP, and qEEG. These techniques require patients to wear electrodes on their heads in order to assess brain activity. The number of electrodes varies from as few as one in the clinical setting to 256 or more electrodes in research studies.

While there is support for the use of neuroimaging to identify the structural and functional changes associated with TBI (Levine et al., 2006), some feel that caution is necessary. For example, Erin Bigler (2001), in his Distinguished Psychologist Award lecture, identified the relationships between TBI and structural brain changes. In contrast, others have indicated that there is little evidence of such damage in MTBI (Lees-Haley, Green, Rohling, Fox, & Allen, 2003). While this disagreement, as well as others, is based on neuroimaging using structural MRI, there is evidence from DTI that subtle alterations in brain structure are associated with TBI as

well as with lower performance on neuropsychological testing (Kraus, Susmaras, Caughlin, Walker, Sweeney, & Little, 2007). These associations between DTI image results and neuropsychological testing have also been found in pediatric studies of TBI (Levin et al., 2008). We examine this issue in the next section.

SPECT imaging shows that regional cerebral blood flow is reduced in symptomatic patients with longstanding MTBI, but with unremarkable structural brain imaging (Bonne et al., 2003). Although the group analysis shows statistically significant differences, the clinical application of brain SPECT imaging in MTBI to associate clinical examination, neuropsychological assessment, and cerebral perfusion at the individual patient level is not available. Therefore, caution should be exercised in using neuroimaging at the individual level of analysis. An additional concern that the TBI damage may alter blood perfusion, thus changing the basis of the BOLD signal in fMRI, has also been raised (Ricker, Hillary, & DeLuca, 2001).

Structure and Function

Normal Participants

Imaging research during the past several decades have attempted to localize functions to different locations, often finding that the brain has a multiple-location activation response pattern to different tasks. It has been possible to localize specific functions to locations or combinations of locations with the different medical technologies. One should keep in mind, however, that the imaging method determines the nature of the results. For example, an fMRI study of verbal memory indicated a temporal lobe (predominantly left) and left frontal lobe activation response pattern in adults (Mazoyer et al., 1993). However, from the CAR perspective, adult verbal memory is a function of broadly activated SCC alpha activity in adults, which involves the left temporal lobe, left hemisphere, and right frontal lobe (Thornton, 2006). The fMRI approach does not examine coherence or SCC relationships. The final understanding will come from a melding of these points of view.

TBI Patients

After experiencing a TBI, the patient's brain function can be altered relative to noninjured brains: this may involve low levels of activation (SPECT studies), greater activation (than normal group) of different regions in response to a task, or activation of different locations (such as the right hemisphere) as well as more loca-

tions. However, these different response patterns do not necessarily lead to lowered functional levels on neuropsychological measures nor have the increased activations necessarily always been tied to success at the task. Specific locations, such as the CC, appear particularly susceptible to white matter damage and DAI. This is discussed separately in this section and in section V.

SPECT/PET Studies

The studies with SPECT/PET technology have generally indicated lowered blood flow (frontal, temporal) under at-rest conditions, increased blood flow under cognitive activation conditions, greater impairment in the TBI patient on more difficult cognitive tasks, greater right hemisphere involvement, failed activations (compared to normative group), and a more dispersed response. TBI patients show decreased blood flow in the frontal cortex (PET studies) or hypometabolism (SPECT; Ricker et al., 2001). Contrary to most SPECT studies, one study actually demonstrated increased blood flow during a cognitive task in the same brain regions that, at rest, demonstrated significant hypometabolism (Duara, Barker, Chang, Yoshii, Loewenstein, & Pascal, 1992). Blood flow (rCBF), however, is not the same as cerebral metabolism. It has been shown that in the TBI patient there is a decoupling of these two measures, which normally function together (Obrist, Langfitt, Jaggi, Cruz, & Gennarelli, 1984), rendering interpretation of results somewhat problematic and reflective of the breakdown of the system in the TBI patient.

MTBI patients are more impaired than controls on the more difficult free-recall measure (Thornton, 2003) and have lower left frontal lobe and increased posterior rCBF, relative to controls, during free and cued retrieval (Ricker et al., 2001). The MTBI patients does not show decreased verbal working memory but does show greater right hemisphere activation and more dispersed activity. Thus the TBI patient appears to activate posterior and right hemisphere locations in response to a verbal memory task, a finding that is echoed in the qEEG results discussed in section V. The increased activations, failed activations (compared to normative group), and right hemisphere involvement are similar to the findings from fMRI (Maruishi, Miyatani, Nakao, & Muranaka, 2007; McAllister et al., 1999) and PET (Christodoulou et al., 2001).

Most SPECT studies, when conducted within the first few weeks post-injury, reveal hypoperfusion associated with MTBI. There is a consistent pattern of hypoperfusion in the frontal and temporal regions across studies (Belanger, Vanderploeg, Curtiss, & Warden,

2007). In one study, however, there were no differences in the resting condition between MTBI and a normal control group in frontal and temporal locations, while there were differences under cognitive challenge (S. H. Chen, Kareken, Fastenau, Trexler, & Hutchins, 2003). When spatial working memory was assessed, the TBI group failed to activate the right frontal location as much as the control group did, although their performance was equal to that of the control group, suggesting a compensatory activity by the TBI group to achieve the same results.

The MTBI patient has also been shown to exhibit hyper-metabolism (vs. controls) in midtemporal and frontal subcortical locations during a continuous performance test (1–5 years post-injury, PET study; Gross, Kling, Henry, Herndon, & Lavretsky, 1996). Retrieval was compared to the input condition. The retrieval condition normally elicits a greater right frontal/temporal pattern of retrieval in the functional neuroimaging literature (Christodoulou et al., 2001). Although the TBI activation pattern was similar to normals; that is, there were more diffusely activated regions, higher levels of activation, and less lateralization. The TBI group displayed greater right frontal lobe activation (superior and middle frontal gyrus) and more errors, whereas controls displayed greater left hemispheric activation in these same regions. There is a consistent pattern in the TBI literature of more diffuse activation in the TBI patient. In summary, the MTBI patient shows changes in rCBF that can differ from the normative group, and the differences are task dependent.

Functional Magnetic Resonance Imaging (fMRI)

The fMRI studies of concussion offer a somewhat confusing picture of the MTBI response pattern compared to control groups with an overall pattern of increased activations in frontal temporal and right frontal areas and increased right hemisphere activation, depending on the task. The increased activations were not related to more successful performance. Diffuse brain activation was found in athletes on memory and sensorimotor tasks relative to pre-concussion baseline (Jantzen, Anderson, Steinberg, & Kelso, 2004). The increased activations on the sensorimotor task were mostly in the frontal/temporal areas, while the level of performance was unchanged. Concussed athletes demonstrated increased left frontal (dorsolateral) activation during a Go-NoGo task, which usually requires the patient to respond to a certain stimulus and not respond to a differ-

ent stimulus (Easdon, Levine, O'Connor, Tisserand, & Hevenor, 2004). In another study, concussed athletes showed reduced activity in the right frontal dorsolateral area during a working memory task, and less activation in the mid-dorsolateral prefrontal cortex, which is a region important for working memory (J. K. Chen, Johnston, Frey, Petrides, Worsley, & Ptito, 2004). In addition, there was a negative correlation between right frontal dorsolateral activation and severity of symptoms. Similarly, hyperactivation in a group of high school athletes assessed 1 week after injury predicted a longer recovery period than for those athletes without fMRI hyperactivation (Lovell et al., 2007).

The effects of MTBI on working memory and simple reaction time were examined by an fMRI study of MTBI patients and controls (McAllister et al., 1999). While the MTBI group did not differ from controls in working memory ability, their brain activation patterns differed. The different brain activation patterns reflect the brain's attempt to provide other resources to accomplish the task, in this case resulting in equal performance to the normative group. The MTBI significantly increased activation compared to the normative group during the high working memory load condition, particularly in the right parietal and right frontal (dorsolateral) regions. The MTBI group's performance was slower in response speed on both the simple reaction time and distractibility tasks of the Continuous Performance Test (CPT). The MTBI patients also reported significantly more symptoms, especially with memory. What is particularly interesting about this study is that researchers attempted to link task success to the activation patterns. The correlation coefficients indicated a significant positive relationship, in the normal group, between left frontal activation and accuracy on the working memory task as well as accuracy on the CPT distractibility subtest. However, in a normal population the CPT task elicits a right frontal activation pattern (Fallgatter & Strik, 1997) thus suggesting that the MTBI patient has adapted a different approach to solving the problem.

The effects of MTBI on reaction time were assessed in an fMRI paradigm (Maruishi et al., 2007). The MTBI patients had confirmed DAI on the basis of MRI lesions. Although the patients did not differ from the controls in the measures of reaction time, their brain activation patterns did differ. While the controls showed activations in the left frontal gyrus, left parietal gyrus, and right inferior parietal gyrus, the DAI patients showed activations in the left inferior frontal gyrus, right inferior frontal gyrus, and right middle frontal gyrus. Analysis of the differences on the reaction time task demonstrated that the DAI patient had significantly greater activation of

the right inferior frontal gyrus, and right middle frontal gyrus than the control participants.

Diffusion Tensor Imaging

Diffusion tensor imaging (DTI) examines the alignment of water molecules in determining white matter tracks. Fractional anisotropy (FA) is a measure of the directional diffusivity of water made through the use of diffusion tensor imaging. A low FA reflects a breakdown in the white matter organization. Further technical explanation is available elsewhere (Le Bihan et al., 2001). The research has very consistent findings in that a low FA is uniformly associated with poorer cognitive abilities.

A striking research finding was reported in a DTI study of MTBI cases. Multiple white matter regions with reduced FA, predominantly involving cerebral lobar white matter, cingulum, and CC were recorded in patients 5.5 months post-injury (Rutgers, Toulgoat, Cazejust, Fillard, Lasjaunias, & Ducreux, 2008). The white matter bundles mostly involved the supratentorial projection fiber bundles, callosal fibers, and fronto-temporo-occipital association fiber bundles. The report indicated that 19% (of 249 white matter fiber bundles) had discontinuity on fiber tracking; in addition, and most importantly, there was no significant relationship between the time interval after injury and the DTI fiber tracking findings. This last finding indicates that the brain does not spontaneously cure itself. A similar finding was observed in qEEG research (Thatcher, Biver, McAlaster, & Salazar, 1998; Thornton, 1999), which is discussed in section V.

DTI studies have not always been consistent in their results, but the overall pattern is one of a strong relationship between DTI FA measures and cognition. For example, while decreased FA was found in 13 studied regions for the moderate to severe TBI group, reduced FA was restricted to the cortico-spinal tract, sagittal stratum, and superior longitudinal fasciculus (bundle of fibers) for the mild TBI group (Kraus et al., 2007).

Reduced FA is associated with impaired learning and memory in moderate and severe TBI (Salmond et al., 2006). Diffusely reduced FA had higher negative correlations with the neuropsychological measures (executive and memory function) than FA measures at individual locations, reflecting the integrative nature of cognition. There are conflicting reports in recent studies of the association of FA and recovery. While one study reported that low white matter FA values at the time of injury were predictive of impaired performance in execu-

tive functioning ability at 6 months post-injury (Miles, Grossman, Johnson, Babb, Diller, & Inglese, 2008), another study concludes that the lower FA in the total CC did indicate higher levels of post-concussion symptoms and emotional distress (Wilde et al., 2008).

However, it has also been shown that specific locations are relevant to specific cognitive abilities, as research shows that there is significant dissociation between cognitive impairments in TBI individuals whose predominant pathology is in the anterior corona radiata or uncinate fasciculus (Ghajar & Ivry, 2008). The anterior corona radiata connects the lateral prefrontal cortex (PFC) with areas such as the thalamus and cerebellum; the uncinate fasciculus is a primary pathway between the lateral PFC and parahippocampal cortex. The TBI patients with shearing in the uncinate fasciculus exhibited deficits in working memory tasks. TBI patients with shearing in the anterior corona radiata exhibited deficits in executive attention (Niogi et al., 2008).

Event-Related Potentials

Electrophysiological measurements of the brain have also proved very sensitive to the effects of a TBI. The qEEG and ERP technologies have improved our scientific understanding of the brain's response to a TBI. Event-related potentials involve the measurement of the magnitude of brain's electrical response pattern within milliseconds of a stimulus (some ERPs go up to 700–800 msec following stimulation). The response can involve several waves of different amplitudes and at different time delays from the stimulus. Each wave has been named and classified as to the proposed processing occurring. The ERP research offers an additional perspective on the TBI patient's cognitive problem and appears to be useful and predictive of cognitive issues. Both the magnitude of the response and the response time were affected negatively in the TBI patient, as we discuss below.

The P300 has been shown in several studies to be a viable indicator of the negative effect of a TBI on the electrophysiology of the brain, mostly in terms of its lower amplitude but also increased time delay from stimulus onset (latency). The P300 (P3) wave is recorded via the EEG as a positive deflection in voltage at a latency of 300 ms from the onset of the stimulus. It is mostly observed in the parietal lobes and is considered involved in cognitive functioning.

Longer reaction times, which are negative findings, were exhibited by symptomatic athletes compared to asymptomatic athletes (Lavoie, Dupuis, Johnston,

Leclerc, & Lassonde, 2004). This effect was not influenced by the length of time since injury. This finding is further support for the hypothesis that there is no spontaneous cure in the TBI patient. There was an inverse relationship between severity of post-concussion symptoms and P300 amplitude. Similar results were found for amplitude of ERPs following MTBI in college athletes (Dupuis, Johnston, Lavoie, Lepore, & Lassonde, 2000). The MTBI patients showed a significant decrease in the amplitude of the waveform around 300 msec (P300), which was negatively related to the severity of post-concussive symptoms; specifically, lower amplitude was associated with more symptoms. MTBI patients with persistent attention and memory impairments have been shown to demonstrate abnormalities in the hippocampally mediated P50 evoked response (Arciniegas et al., 1999; Arciniegas & Topkoff, 2004) and the frontocentral P300 response (Arciniegas, Anderson, Topkoff, & McAllister, 2005; Pratap-Chand, Sinniah, & Salem, 1988; Schatz & Zillmer, 2003).

Reduction in the amplitude of N1, P2, and P3 components, which indicate the early and late stages of auditory processing, were found in symptomatic and asymptomatic athletes with TBI in comparison to control athletes on an auditory oddball task (Gosselin, Theriault, Leclerc, Montplaisir, & Lassonde, 2006). An oddball task generally requires the patient to respond differently when a specific rare stimulus is presented. There were no group differences in the reaction times or in latency of the ERP components, except for P3 latency, in which the controls showed a shorter latency than the MTBI group. Headaches and concentration problems were both negatively correlated with the amplitude of the P3 component. These results, as the researchers amply suggest, challenge the practice of returning the non-symptomatic athlete to competition.

The effects of multiple concussions in athletes were examined in a visual oddball task (De Beaumont, Brisson, Lassonde, & Jolicoeur, 2007). Three groups were compared on neuropsychological measures as well as P300: athletes with no history of concussion, those with one concussion (mean time of 59 months since incident), and those with more than one concussion (mean time since of 31 months since last concussion). While there were no differences on neuropsychological measures between the three groups, the multiple-concussion group showed reduced P3 amplitudes compared to the other two groups some 2.5 years after the injury. In conclusion, the P300 appears to be a viable measure of the brain's response to the trauma in that reduced amplitudes and longer delays are associated with brain dysfunction.

Corpus Callosum

Much of the research has implicated the CC, which connects the two hemispheres, as one of the major sites of injury. This discussion focuses on the CC while acknowledging that there is evidence in the literature of effects of TBI on other brain structures. The other affected areas include the gray-white matter interface, dorsolateral aspect of brain stem, subcortical white matter, basal ganglia, and body and posterior (splenium) section of the CC and cerebellum (Parizel et al., 1998).

The CC is the largest white matter tract in the brain and has long been considered to be vulnerable to TBI (Gorrie, Duflou, Brown, Gibson, & Waite, 2001). Shear-strain mechanisms are common in the splenium (Gennarelli et al., 1982; Gentry, Thompson, & Godersky, 1988; Mendelsohn, Levin, Harward, & Bruce, 1992). Autopsy studies of MTBI patients who died of unrelated causes showed that the CC was the most frequent site of DAI, which is followed by the brain stem and then white matter in the lobes (Belanger et al., 2007). Thus, even in MTBI cases, DAI effects have been found. Atrophy of the CC is found in the TBI patient for both adults (Anderson, Bigler, & Blatter, 1995; Gale, Johnson, Bigler, & Blatter, 1995; Levin et al., 2000) and children (Levin et al., 2000). Interestingly, the longer the coma lasts, the more the callosal volume reduction (Tomaiuolo et al., 2004). Measures of memory were positively associated with volume of selected structures. For example, immediate free recall of word lists positively correlated with the volume of the fornix and the CC. Delayed recall of word lists and immediate recall of the Rey figure both positively correlated with the volume of the fornix. Delayed recall of the Rey figure positively correlated with the volume of the fornix and the right hippocampus. Thus differential cognitive effects are found with damage to different structures. MTBI is associated with reduced FA in the white matter, compared to controls, most notably in the internal capsule and CC, despite normal-appearing white matter on MRI (Arfanakis, Hermann, Rogers, Carew, Seidenberg, & Meyerand, 2002). The FA reduction was often less evident 1 month after injury. However, even if the time frame is extended to 18 months, reductions in CC FA have been reported in adults with TBI (Rugg-Gunn, Symms, Barker, Greenwood, & Duncan, 2001).

Pediatric TBI patients exhibited decreased mean FA in the splenium of the CC, compared to matched controls, irrespective of the presence or location of specific callosal or extra-callosal focal injury (Wilde et al., 2008). This pattern was also present in anterior regions of the CC despite the absence of focal lesions. Lesions

in the splenium were found in only 25% of the children despite decreased mean FA. Higher FA was related to increased cognitive processing speed and faster interference resolution on an inhibition task. In the pediatric TBI patients, higher FA was related to better functional outcome as measured by the dichotomized Glasgow Outcome Scale. In conclusion, the CC shows evidence of dysfunction immediately after a MTBI, 18 months later, and at autopsy.

Inconsistencies in Anterior Corpus Callosum Response

The Stroop task elicited the normal fMRI response pattern (frontal, occipital, parietal) in five recovering severe TBI patients, except for a decrease in activation of the anterior CC (ACC) (Soeda, Nakashima, Okumura, Kuwata, Shinoda, & Iwama, 2005). The TBI patients (1–7 years post-injury) generally did as well as the control participants on the Stroop but manifested poor memory for recent events and had trouble with their jobs. In a functional PET study, TBI patients increased their activity in the ACC and in frontal and occipital lobe activity during working memory tasks (Levine, Cabeza, McIntosh, Black, Grady, & Stuss, 2002).

Greater Effort in the TBI patient

One hypothesis that has arisen as a result of the research is that the TBI patient engages in greater subjective “cognitive effort” to attain the same objective level of cognitive performance as controls (Braver et al., 1997) on the same tasks. TBI patients often report that they must now “work harder” to perform previously simple tasks. How this “effort” is translated to medical imaging measures and qEEG measures is undetermined at this point, although subjective and objective greater cognitive load may involve greater frontal lobe involvement, which may reflect “greater effort” (Braver et al., 1997). Data presented in section V indicate that greater levels of beta activity in the frontal lobe are characteristic of the TBI patient’s response pattern to cognitive tasks and thus may reflect the subjective experience of greater effort.

A comparison of patients with orthopedic injury (OI) to TBI patients (moderate to severe at 3 months post-injury) found that the frontal (cingulate, medial frontal, middle frontal, and superior frontal gyrus regions) brain activation during a stimulus-response incompatibility task is greater in TBI patients than in OI patients and is positively related to TBI severity (Schei-

bel et al., 2007). The number of lesions in the TBI group do not relate to the degree of activation elicited. In addition, the more severe TBI patients (i.e., lower GCS) have greater activation within deeper structures that include the basal ganglia, thalamus, anterior cingulate gyrus, and CC. The researchers had speculated that DAI, rather than contusions and other focal pathology, may be responsible for the increased activation. The report also indicated a positive relationship between activation (anterior cingulate gyrus, medial frontal, parietal regions, as well as brain stem) and response accuracy during a stimulus-response incompatibility task for the OI, but not the TBI patients, indicating increases in activation results in performance benefits for the OI patient but not the TBI group. The task involved a stimulus-and-response feature that involved either the same side of the body (e.g., right-hand response to a visual stimulus presented on the right side) or a different side of the body (e.g., right-hand response to a left-sided visual stimulus).

Another fMRI study of working memory showed greater activation for patients with moderate and severe TBI with DAI (Turner & Levine, 2008). The patients had greater activation than controls in frontal lobe (left middle frontal, right inferior) as well as bilateral parietal and left temporo-occipital areas. The TBI patients showed these brain activation differences despite performance equal to that of the control group.

In conclusion, the medical imaging literature has provided evidence of damage to the TBI brain in the MTBI cases. The pattern is one of increased arousal (compared to the normative group) on relatively simple tasks, breakdown on more difficult tasks, disconnection between regions, and increased employment of frontal and right hemisphere locations. The possible clinical implications are that the TBI patient is (1) trying harder to deal with simple tasks, (2) cognitively breaks down under complex situations, (3) is not employing the more verbally oriented left hemisphere, and (4) is employing the more emotional/spatially oriented right hemisphere.

SECTION IV

Neuropsychological Testing

The clinician needs to know the cognitive, behavioral, and emotional issues of the TBI patient to develop a treatment plan. This section addresses what science knows and the problem of the limitations of science in understanding the cognitive and emotional effects of a

TBI. Neuropsychological tests have been the standard for assessing cognitive functioning following TBI. Surprisingly, up to 90% of the “recovered” cases of moderate TBI continue to have cognitive deficits on neuropsychological testing (Rimel et al., 1981). The clinician should be aware that neuropsychological measures have suffered from problems in interpretation, which include such issues as:

- (1) A valid pre-trauma baseline
- (2) Possibility of malingering
- (3) Relationship to medical imaging results
- (4) Psychometric issues: retesting effects, availability of valid and reliable parallel forms of measures, discriminate sensitivity to other conditions (such as preexisting learning disabilities)
- (5) Differential diagnosis in relation to preexisting conditions
- (6) Relationship to outcome measures (job, etc.)
- (7) Relationship to depression and other emotional and behavioral conditions.

These topics lead to questions concerning the validity of interpretation of results, which should alert the clinician to be cautious in blindly accepting conclusions in reports. However, some valid assumptions regarding baseline functioning can be made in the absence of pre-incident data and give validity to neuropsychological conclusions. For example, a patient who was a straight-A student throughout his academic career and, following a TBI, is performing two standard deviations below the normative group on a particular test cannot be considered unaffected by the TBI in the absence of other possible causes. In addition, without evidence to the contrary, most individuals (68%) can be expected to fall within one standard deviation range on a test, and about 95% within two standard deviations, providing a basis for some reasonable interpretations of deficits on tests. Therefore a neuropsychologist can, on occasion, correctly infer that an individual's preexisting condition was above his presently tested functional level on measures and thus accurately infer the presence of brain damage.

Pre-Trauma Baseline

In both the military and sports the problem of pre-trauma baseline testing is understood and is beginning to be addressed. The pre-trauma baseline problem refers to the problem of determining if there is a deficit in functioning based on post-trauma testing performance. If a subject is performing at a normal level, it doesn't

necessarily mean that the TBI has had no effect, as the subject may have been performing well above the normal range prior the injury. To establish an effect of a TBI, the evaluator needs to have some measure or estimate of what the pre-morbid level of functioning was on a particular measure.

In sports and military studies involving computerized cognitive batteries such as the ImPACT instrument (Iverson, Lovell, & Collins, 2003), the Concussion Sentinel (Erlanger, 2002), and Automated Neuropsychological Assessment Matrices (Reeves, Culligan, LaCour, Raynsford, Elsmore, & Winter, 2001) are being employed to establish baselines. However, pre-trauma baseline data are typically unavailable in injuries resulting from motor vehicle accidents, falls, and assault, and the best that can be obtained is school records, which are far from an ideal baseline. Even with the availability of pre-trauma neuropsychological data, there are problems of retesting within short time frames, even on alternate forms. There is the additional problem of the brain's physical adaptation, which can result in normal scores despite evidence of physical damage. In addition, it has been demonstrated at a 4-month retest interval that improvements on assessment measures (ANAM) can significantly improve in noninjured athletes (Daniel et al., 1999). So if the practice effect or cognitive improvement can occur at 4 months, then how can we rely upon measures that use return to preexisting level as the criterion of recovery? We should, rather, use improvement from baseline as the guideline.

Neuropsychological testing is especially useful when baseline studies are obtained and compared with post-injury examinations (Echemendia, Putukian, Mackin, Julian, & Shoss, 2001). For example, neuropsychological testing was useful in detecting cognitive impairment in college athletes following MTBI and was more effective than subjective report in differentiating injured from non-injured athletes (Echemendia et al., 2001). The addition of the ImPACT computerized battery to the subjective report increased diagnostic accuracy by 19% (van Kampen, Lovell, Pardini, Collins, & Fu, 2006).

This research challenges the assumption that the patient is the best judge of the cognitive effects of his or her own injury. However, not everyone favors a widespread adoption of neuropsychological testing. For example, one view is that due to time/financial costs of testing, the lack of validation in determining recovery, the limited validation and utility of diagnosing concussion, and numerous logistical concerns, the widespread use of such testing is not viable (Grindel, 2006).

Malingering

The clinician needs to monitor the athlete's motivation for performance in the post-concussion evaluation (Bailey, Echemendia, & Arnett, 2006). In the sports arena the tendency is to minimize/deny effects. In the personal injury realm the tendency is to exaggerate/fabricate effects. The possibility of malingering has been a major focus in neuropsychological testing for a number of years, and assessment of malingering is presently recommended by the National Academy of Neuropsychology as part of a neuropsychological assessment (Bush et al., 2005). In most neuropsychological evaluations the goal is to determine the presence of exaggeration, not minimization, of cognitive deficits. However, interpretations of the results of the malingering batteries face problems in validity. Many of the research reports appear to implicitly assume that because someone is litigating the case, the patient must be malingering, and then proceed to show data of "exaggerated" complaints. However, it is equally plausible that the patient who is experiencing more symptoms is more likely to litigate. Historically, judgments were based solely upon clinical testing data, as medical imaging technology (CT, MRI) was not able to provide sufficient basis to provide viable alternate data. In addition, in most situations the patient has not even undergone relevant physical assessment. The imaging studies using DTI, ERP, and qEEG have proved to be the most sensitive and relevant to the underlying physical damage caused by the trauma and thus offer a more valid and useful assessment approach to malingering than paper-and-pencil or computerized neuropsychological measures. The most valid medically diagnostic instruments (qEEG, DTI) are seldom used to address the question of malingering. The qEEG results are discussed in section V.

Empirical studies of malingering in litigation offer perspectives in contrast to the assumption that all patients with symptoms persisting months after TBI are malingerers. For example, one study estimates that while 57% of TBI patients complained of symptoms at the time of the medicolegal report (mean interval 9–12 months), 39% had symptoms at the time of settlement (mean interval 22–1 months) and 34% had symptoms 1 year after litigation (Fee & Rutherford, 1988). If litigants were all malingerers, then the question that can be raised is why there was any reduction in symptoms from the report time period to the settlement and why was there only a 5% decrease in symptoms after the settlement. The possible counterargument is that the claimant was just continuing to present malingered symptoms to avoid the possible reopening of the case.

However, it would be unlikely that a case would be reopened once the patient claimed the symptoms were gone. A meta-analytic review of 18 studies of 2,353 individuals with TBI of varying severity was used to explore the relationship between litigation and symptoms (Binder & Rohling, 1996). The conclusion of the review was that financial incentives may account for 20%–25% of the persistent signs and symptoms. However, in the absence of a clear physical definition of TBI, any estimate is suspect. Other studies have failed to find associations between compensation or litigation and frequency or severity of post-concussive symptoms (Keshavan, Channabasavanna, & Reddy, 1981; Merskey & Woodforde, 1972; Rimel et al., 1981). Although base rates of the concussion symptoms are an important consideration, it is perhaps more valid to establish the pre-accident symptom base rate for the individual TBI patient, which is problematic.

In conclusion, while it most certainly is the case that malingering exists, neuropsychological or psychological reports which that statements on a patient's motivational state and infer malingering need to be taken with caution. Frequently relevant physical (DTI, qEEG) diagnostic tests are not available to confirm or deny assertions of malingering. In addition, lack of structural damage on the CT and MRI instruments is not evidence of malingering due to the low frequency of structural deficits in MTBI cases. Two decades ago, many symptomatic patients had normal MRI scans (Levin et al., 1987). More recent estimates continue to indicate that 43%–68% of mild TBI patients have normal structural MRI scans (Hofman, Stapert, van Kroonenburgh, Jolles, de Kruijk, & Wilmlink, 2001; D. G. Hughes, Jackson, Mason, Berry, Hollis, & Yates, 2004).

Relationship Between Neuropsychology and Medical Imaging Technologies

Neuropsychological measures and medical imaging techniques have not reached a level of sophistication that always allows us to identify the relationship between specific neuropsychological deficits and a lesion in a particular locations, or sets of lesions in different locations. Part of this problem resides in our present understanding of the mind-body problem. The following results provide some research information on the complexity of the problem facing this field.

In a group of TBI patients, neuropsychological functioning improved while DTI fractional anisotropy (FA), mean diffusivity (MD) from the DTI images, and voxel-based analyses of the gray matter (GM) and white

matter (WM) probability maps revealed significantly greater negative gray and white matter change over time (2 months vs. 12.7 months post-injury) in patients compared to controls (Bendlin et al., 2008). This line of evidence supports Thornton's (2000) assertion that there is no spontaneous cure of the underlying physical damage in the TBI patient, and in this case, the underlying physical damage worsened. The TBI affected all the major fiber bundles in the brain, which include CC, cingulum, superior and inferior longitudinal fasciculus, uncinate fasciculus, and brain stem fiber tracts. Thus improved neuropsychological testing doesn't necessarily mean that the brain has repaired itself. In this example, it would appear that the brain found some way to change its physical response, as it couldn't rely upon the injured white matter tracts to function as well. The neuropsychological testing may not have been sensitive enough to reveal the underlying physical damage. The counterargument to this interpretation is that the brain has found a different and equally effective way to solve the problem due to its adaptive nature, albeit with limitations with more complex and demanding tasks (Thornton, 2003).

Psychometric Issues: Retest Effects, Alternate Forms

The additional issues of retest effects have availability of valid alternate forms have been traditional areas of concern in psychological assessment and are not specific to the TBI literature.

In the sports arena, the problem has drawn considerable attention. The ImPACT test is a popular screening measure for sports concussion (Schatz, Pardini, Lovell, Collins, & Podell, 2006). Test-retest reliability values of the ImPACT test range from .15 to .61 in a group of 115 normal participants retested at 45 and 50 days following original evaluation (Broglia, Macciocchi, & Ferrara, 2007). These low reliability values render the test statistically unacceptable for these time periods. The other measures assessed by Schatz et al. (2006) included the Concussion Sentinel and the Headminder Concussion Resolution Index. The researchers concluded that these instruments also demonstrated similar low reliability values. The false positive rate, which identifies a normal individual as a concussed patient, was 38% at 45 days for the ImPACT tests, 19% for the Headminder Concussion Resolution Index and 33% for the Concussion Sentinel. Other researchers have reported higher reliabilities for shorter periods of time. For example, there are no significant practice effects in normals on

the ImPACT measure when tested within several days (Iverson et al., 2003). The ImPACT test has also been shown to correctly identify mildly concussed athletes (Schatz et al., 2006). However, Broglia et al. (2007) concluded that currently no assessment test could be recommended. In addition, without equivalent alternate forms, the "improvements" on these measures taken within days of each other are susceptible to practice effects. Similar conclusions were reached regarding computerized testing in the sports concussion area based upon cost, validity, and reliability issues (Grindel, 2006; Randolph, McCrea, & Barr, 2005). Even with equivalent forms the validity of repeat testing within a short period of time opens up the potential effect of practice on the results. Other researchers have argued that following a single repetition of a test there is no further evidence of a practice effect on computerized tasks (Collie et al., 2006). For example, in one study the researchers studied three groups of athletes (control, symptomatic concussed athletes, and asymptomatic concussed athletes) and conducted repeated computerized testing. Following the TBI, the asymptomatic athletes had difficulty with only the divided attention task, not the motor or attentional tasks. In contrast, the symptomatic group demonstrated large and significant deficits on almost all the measures of reaction time and attention, especially on tasks assessing speed. Both the control and asymptomatic groups significantly improved on repeat computerized testing, from pre-season baseline to post-injury for asymptomatic group. This demonstrates the problem of repeat testing. However, the symptomatic group's performance on paper-and-pencil tests did not deteriorate despite significant deficits on the computerized battery, calling into question the validity of paper and pencil neuropsychological testing instruments. The presence and duration of LOC and PTA did not differentiate between the symptomatic and asymptomatic groups. Erlanger et al. (2001) addressed the complexity of this problem with respect to a Web-based neuropsychological test protocol and reported that the Concussion Resolution Index showed resistance to practice effects. Researchers have argued that a .90 test-retest reliability measure is the appropriate statistical criteria for clinical and research use of a test (Randolph et al., 2005).

The reliability problem relates to the underlying true value of a variable. Confidence intervals employ high and low values that reflect different probability values (95%, 98%, etc.) of the true value within the assigned range. As the reliability decreases, the confidence interval of a test score becomes larger, thus compromising the ability to make definitive probability

statements regarding the significance of the difference between two administrations of a measure. For example, the Wechsler IQ measures have a mean of 100, an *SD* of 15, and reliability of .90. When 95% confidence intervals are used, a 7-point drop is statistically significant (Randolph et al., 2005). As the reliability of a measure decreases, there is more uncertainty regarding the true value, and thus a wider confidence interval to enable a similar probability value. If the reliability of the IQ test was .70, it would require a 20-point drop in IQ to be significant. It is relevant for the clinician to understand these issues when presented with reports of lack of progress in a treatment program.

Differential Diagnosis

Differentiating the effects of a TBI from a preexisting learning disability, a previous TBI, or other CNS-damaging events has always been extremely problematic. The availability of academic records (grades, SAT scores) is only occasionally useful, due to the lack of equivalence of these measures to neuropsychological measures. High schools do not generally administer neuropsychological batteries. On occasion, a previous child study team evaluation can be useful.

Relationship Between Neuropsychological Measures and Real-World Outcome

The association between neuropsychological status and functional impairment was examined with equation modeling in 87 patients with moderate to severe TBI studied longitudinally (Rassovsky et al., 2006). The results of the modeling showed that only neuropsychological status, not emotional or behavioral difficulties, consistently mediated the relationship between TBI severity and functional outcome at 12 months post-injury. No direct effect of injury severity on functional outcome was found. Rather, it was the indirect effect that was found to be significant, suggesting that other intervening variables mediate the relationship between injury severity and functional outcome. Some studies of MTBI show support for a relationship between severity of neuropsychological deficits and various outcome measures, including employment status (Ross, Millis, & Rosenthal, 1997). However, concerning the relationship between injury severity and neuropsychological status, research studies have found only a weak relationship between these parameters (Binder et al., 1997). Other researchers have found that other factors, such as pre-morbid IQ, emotional functioning, and financial incen-

tives, may exert a larger effect on outcome than injury severity (Binder & Rohling, 1996). A review of the literature concludes that many neuropsychological tests have a moderate level of ecological validity predicting everyday cognitive functioning (Chaytor & Schmitter-Edgecombe, 2003). Specifically, high scores on tests predicted full-time employment 62% of the time, while low scores predicted unemployment 67% of the time (Fabiano & Crewe, 1995).

Depression, Brain Structures, Cognition, and Personality Changes in TBI

Depression

There is a large body of evidence indicating that depression is a common complication of TBI, with a prevalence of 16%–61% meeting criteria for major depressive disorder. This high variability suggests problems in the diagnostic methods used, or variability in sampling methods, such as randomization versus self-selection, and recruitment patterns (Kim et al., 2007). Depression is the most cited psychological disturbance after TBI, with prevalence rates ranging from 6% in cases of mild traumatic brain injury to 77% in more severe TBI within the first year after injury (Jorge, Robinson, Starkstein, & Arndt, 1993). For example, 91 consecutive TBI patients admitted to a general hospital at 3, 6, 9, and 12 months post-injury were compared for depression with 27 patients admitted for multiple traumas without TBI (Jorge et al., 1993). In the TBI sample, 52% met *DSM-IV* criteria for mood disorder due to TBI, 33% had major depressive features, 10% had depressive features, and 9% had either manic or mixed features. In the comparison group, 7% had major depression, and 15% had depression without major depressive features. Retired professional football players ($N = 2,552$) with an average age of 53.8 years and an average professional football-playing career of 6.6 years were administered a general health questionnaire that included questions about prior injuries, the SF-36 (Short Form 36), and other markers for depression (Guskiewicz et al., 2007). Eleven percent of 2,434 athletes reported having prior or current diagnosis of clinical depression.

There was an association between recurrent concussion and diagnosis of lifetime depression, suggesting that the depression prevalence increases with increasing concussion history. Compared with retired players with no history of concussion, retired players reporting three or more previous concussions (24%) were 3 times more likely to be diagnosed with depression; those with a history of one or two previous concussions

(36%), were 1.5 times more likely to be diagnosed with depression. An MTBI group with LOC of 15 minutes experienced more depression than a severe TBI group (Alexander, 1992). World War II veterans were assessed for prevalence of depression several decades after the initial injury (Holsinger et al., 2002). After age, education, and health conditions were accounted for, an 18% lifetime prevalence of depression was observed in veterans who suffered a head injury in their 20s, which was significantly higher than the observed 13% lifetime prevalence for those without a history of head injury.

Depression and Brain Structure Relationship

The following discussion provides evidence of the occurrence of emotional and personality changes in the TBI patient. However, it should be kept in mind that there is an implicit confusion in this type of literature. The fact that we are able to indicate a certain percentage of TBI patients are depressed doesn't mean that we can state unequivocally that the TBI is the cause of the depression. The problem resides in our inability to state whether the causal link is the physical effect on the brain or the sequelae of the TBI on psychological, cognitive, social, and economic functioning. For example, has the patient become depressed because recall of events is poor, or because life has changed since the TBI, or because as a consequence of the TBI the patient cannot pay bills and has lost employment?

The alternate to the environmental or psychological cause of the depression is a physical one, which is that the TBI results in a brain response pattern that is present in depressed individuals, and thus the patient is physiologically depressed. Patients with major depression alone tend to have left anterior hemisphere lesions, while depression with anxiety is associated with right hemisphere lesions (Jorge et al., 1993). qEEG measures of prefrontal activation asymmetry at rest showed that patients with greater relative left prefrontal activation report more positive and less negative moods (Davidson, Coe, Dolski, & Donzella, 1999). In addition, acutely depressed patients as well as remitted depressed patients exhibit decreased left prefrontal activation compared with never-depressed controls. There is evidence suggesting that damage to the basal ganglia or frontostriatal tracts may play a role in depression following head injury. One study found that head trauma resulting in frontal (left dorsolateral frontal) and/or subcortical (left basal ganglia) lesions was associated with the highest rates of depressive episodes (Fedoroff et al., 1992). In other samples with prior head injury, there is evidence for involvement of subcortical (basal ganglia) (Steffens,

Helms, Krishnan, & Burke, 1999) and frontal (ventromedial orbitofrontal area) locations in depression (Elliott et al., 1997). As this chapter has elucidated, it is well known that a TBI affects frontal lobe functioning.

TBI patients with MRI identified lateral lesions demonstrate, at 3 months post-injury, more intense depression, greater problems in social skills and daily living, and more apathy than patients with medial lesions (Paradiso, Chemerinski, Yazici, Tartaro, & Robinson, 1999). Major depression in TBI is also associated with reported smaller hippocampal and amygdala volumes, structural and morphological changes in the prefrontal and orbitofrontal cortex, and basal ganglia structures (Guskiewicz et al., 2007). Studies that fail to address the issue of brain-based versus environmentally based depression or anxiety will not offer clarity to this problem.

Depression and Cognition

Given the above qualifications it remains relevant to the clinician to know about the possible role of a TBI in his or her patient's history as a possible contributory factor to depression. The large presence of depression in the TBI group also raises the question of whether depression could be affecting the cognitive measures associated with mild and moderate TBI. TBI patients with major depression (28%), relative to nondepressed TBI, were found to have significantly lower scores on measures of working memory, processing speed, verbal memory, and executive function (Rapoport, McCullagh, Shammi, & Feinstein, 2005). The differences averaged about .45 *SD* advantage for nondepressed. This is similar to the deficit of .50 *SD* on the California Verbal Learning test (CVLT) found in major depression patients in a psychiatric hospital (Otto, Bruder, Fava, Delis, Quitkin, & Rosenbaum, 1994). TBI patients (200 days post-injury and 28% with major depression) were found to have significantly lower scores on measures of working memory, verbal memory, executive function, and processing speed than the control group (Rapoport et al., 2005). This study demonstrated that at 6 months following mild and moderate TBI, major depression is associated with worse performance across an array of cognitive domains, including attention, memory, and executive functioning. While more than half of the patients without major depression were unimpaired on any cognitive test, this was true for only 15% of the patients with major depression. The literature has generally been reporting negative or conflicting results in this area, leaving the question of the influence of depression on memory functioning in the TBI patient unresolved, although suggestive of a negative influence.

Post-Traumatic Stress Disorder and Brain Structures

The physical measurement of PTSD offers an inconsistent set of results. An fMRI evaluation of PTSD showed significantly less activation of the thalamus, the anterior cingulate gyrus (Brodmann's area 32), and the medial frontal gyrus (Brodmann's area 10/11) than a comparison group (Lanius et al., 2001). However, contrary to that finding is the observation that combat-related PTSD soldiers had increased beta power over frontal regions relative to veterans without PTSD (Begic, Hotujac, & Jokic-Begic, 2001). Risk of PTSD was directly associated with the volume of left temporal lesions in MRI scans in 95 pediatric patients with TBI (Vasa et al., 2004). Left orbitofrontal lesions were associated with decreased risk of hyperarousal symptoms, while diffuse brain lesions were related to increased risk of avoidant symptoms.

In MTBI, depression, and PTSD, the frontal lobes are affected, as well as other structures. The task of differentiating between these diagnostic categories based upon frontal lobe problems is challenging. Definitive statements regarding the causality of neuropsychological problems in these groups becomes extremely problematic, as we have only (1) a limited understanding of how some of these neuropsychological tasks function with respect to brain structures and (2) a limited understanding of how PTSD and MTBI affect brain structures and functions. To render a definitive statement that the depression, not MTBI or PTSD, is affecting the memory system would require knowledge that a specific brain structure is involved in memory and is not affected structurally or functionally by PTSD or MTBI. The qEEG appears to be particularly well suited, once research has discovered the different qEEG patterns for PTSD and MTBI, to address simultaneously both cognition and emotional states.

Personality Changes

A study of children ages 5–14 with TBI found personality changes in 22% of participants between 6 and 12 months after injury, and 12%–13% in the second year after injury (Max et al., 2006). The severity of injury consistently predicted personality change, and pre-injury adaptive function predicted personality change only in the second year post-injury. Superior frontal gyrus lesions were associated with personality change between 6 and 12 months following injury, after severity of injury and the presence of other brain lesions were controlled for. Only lesions in the frontal lobe white matter were significantly related to personality change

in the second year after injury. Emotional instability was the most common subtype of the disorder, followed by the aggressive subtype and then the disinhibited subtype. The other two personality changes described were the rare and generally resolving apathetic and paranoid subtypes. A review of the literature from 1978 to 2006 found a large prevalence of psychiatric disorders following nonpenetrating TBI (Kim et al., 2007). The disorders were psychosis (20%), depression (18%–61%); PTSD (3%–59%), mania (83%–22%), and aggression (20%–40%). However, as indicated by the authors of the study, the prevalence needs to be confirmed in controlled studies.

SECTION V

The Role of the Quantitative EEG in the Assessment and Rehabilitation of the TBI Patient

This section provides (1) a basic understanding of the qEEG in terms of the frequencies, variables and locations employed; (2) information on what is presently known about the relationship between the qEEG variables and TBI; (3) a brief history of the relationship between the qEEG and the field of EEG biofeedback; (4) a description of the activation qEEG model of evaluation and the resultant Coordinated Allocation of Resource model of brain function; (5) a discussion of the qEEG correlates of auditory and reading functioning; (6) principles of intervention and results with the TBI patient; (7) a comparison of the TBI and normal response pattern in the auditory processing task with particular attention to the CC; and (8) information on the rehabilitation of the TBI patient with specific examples.

The 10–20 System

The brain produces electrical signals in the range of 40–100 microvolts, which are detected by the electrodes. Due to differences in skull thickness, the microvolt levels can vary in that thicker skulls don't allow the electrical energy to be transmitted as easily, resulting in lower microvolt levels than thinner skulls. The EEG data, once collected, need to undergo an artifacting analysis. Artifacts are signals that are not due to brain activity but are mostly due to eye movements, muscle activity, or other non-brain events. Software programs typically allow the evaluator to mark the epoch (a period of time) as deleted due to artifact presence. The data are then analyzed by

software and compared to an available database. Presently almost all databases are eyes closed. None have evaluated the relationship between the qEEG variables and task success and most do not extend the frequency range above 21 Hz (sine waves per second).

Figure 18.1 presents the standard nomenclature of the 10–20 system. The 10–20 system standardizes the electrode location to similar anatomical locations despite the differences in head size among patients. Nylon caps that have the electrodes located in the 10–20 system are typically employed; caps are available in different sizes to fit the age span from infants to adults. The letter F refers to frontal, T to temporal, C to central, P to parietal, and O to occipital locations. Left hemisphere locations are indicated by odd numbers, and right hemisphere locations by even numbers. Typically what occurs in a qEEG recording is that the electro-cap is placed on the head, and ear reference electrodes are attached to the ear lobes. The nylon caps have tin plates that are separated from the scalp by a small space, which is filled with electro-gel to enable conductance of the electrical energy from the scalp to the tin plate. Figure 18.2 presents a visual representation of the different frequencies.

The following discussion provides a description of the qEEG measures. Not all the measures have proved to be correlated with cognitive performance. The descriptions are provided, as other researchers have reported

significant findings with these variables. From Thornton's (2001) viewpoint and data with the TBI population, learning disabilities, and attention deficit disorders, there are two classes of critical variables, each of which has two critical variables. The first general class involves what is happening at a specific location and measures the different frequencies in terms of their relative power and microvolt values. The second class involves the similarity of the waveforms between different locations with such measures as the Spectral Correlation Coefficient (SCC) or coherence and phase. The phase measure is a more time-sensitive measure of the SCC. The second measures are reflective of the activity in the long myelinated fibers connecting the locations. The connection issues have been addressed with several different conceptual (coherence, co-modulation, spectral correlation, phase) and mathematical definitions (Collura, 2008). It is empirically unclear, at this point, how these different methods of calculating these relationships interrelate, as well as how they relate to cognition. The exception to this statement is the Thornton (2001) research that employed the Lexicor Spectral Correlation Coefficient measure and correlated the qEEG measures with cognitive measures. Thornton's research has found that three variables (relative power, SCC, and phase values) are the most useful in predicting cognitive effectiveness and understanding the effect of a TBI on the brain's electrophysiology. The reports by other researchers on coherence employ their own specific definitions.

Definitions of Measures

Microvolt. The average strength in absolute microvolts of the signal of a band during an epoch. This measure merely reflects how strong the signal is in terms of microvolts.

Relative power. The microvolts of the particular band divided by the total microvolts generated by all bands at a location, averaged over the epoch time period. This measure is insensitive to skull thickness, as it measures the total microvolts at a location and determines the percentage of the total microvolts that are within a particular frequency range.

Peak frequency. The peak frequency of a band during an epoch (defined in frequency)

Peak amplitude. The peak amplitude (measured in microvolts) of a band during an epoch.

Symmetry. The peak amplitude symmetry between two locations in a particular bandwidth—defined as $(\text{location A} - \text{location B}) / (\text{location A} + \text{location B})$, where A and B represent two locations of the 10–20 system.

Figure 18.1 Standard 10-20 system and nomenclature for locations.

Figure 18.2 The different frequencies.

Spectral correlation coefficient. The average amplitude similarity between the waveforms of a particular band in two locations over an epoch. This variable is defined within a particular frequency range.

Phase. The time lag between two locations (A and B), in the 10–20 system, of a particular band as defined by how soon after the beginning of an epoch a particular waveform at location A is matched in amplitude at location B. The measurement time period for this variable is considerably less than for the SCC variable and can occur over a period of milliseconds.

The qEEG and TBI

The qEEG has been shown to have higher discriminant function rates than other standard EEG or MRI technologies in differentiating TBI from normal participants. For example, researchers in the TBI field have argued that routine EEG and MRI measures are not useful in TBI

identification due to their low sensitivity and reliability in discerning mild to moderate TBI (e.g., under 20% accuracy; Thatcher et al., 1998). qEEG has been used to differentiate between 608 MTBI adult patients and 108 age-matched controls with an accuracy rate of about 90% (Thatcher, Walker, Gerson, & Geisler, 1989). Moderate to severe cases were not included in the analysis. The useful qEEG measures included increased frontal theta coherence (Fp1-F3), decreased frontal beta (13–22 Hz) phase (Fp2-F4, F3-F4), increased coherence beta (T3-T5, C3-P3), and reduced posterior relative power alpha (P3, P4, T5, T6, O1, O2, T4). Three independent cross validations resulted in accuracy rates of 84%, 93%, and 90%. The prognostic efficacy of qEEG was compared to that of GCS, brain stem auditory evoked potentials, and CT in 162 TBI coma patients recorded 1–21 days after injury (Thatcher, Cantor, McAlaster, Geisler, & Krause, 1991). The EEG results and the GCS score at the time proved to be an effective discriminant

(96% accuracy) between good outcome and death, with EEG phase measurements accounting for 44% of the variance in outcome, followed by EEG coherence values. The researchers suggested that the phase and coherence values may reflect DAI severity issues. Significantly higher power in the delta band and lower power in the alpha band were found for a TBI group compared with matched controls in an eyes-closed task (Korn, Golan, Melamed, Pascual-Marqui, & Friedman, 2005). Changes in spectral EEG recordings were superior to the GCS and brain stem evoked potentials in determining outcome in a group of 29 comatose patients (Alster, Pratt, & Feinsod, 1993). Improvement on spectral EEG recordings in the alpha and beta bands were related to improvements on GCS measures over time, while the delta frequency positively correlated with the depth of coma. In either case, the EEG and ERP information is providing useful information in the TBI situation.

qEEG techniques were integrated with conventional MRI to explore the shift in the water proton relaxation times in moderate to severe TBI (Thatcher et al., 1998). Nuclear magnetic resonance of brain water proton T2 relaxation times, determined by the proton density within various tissue compartments, and absolute microvolt measures of the qEEG were obtained from 19 moderate to severe TBI (1.7 years post-accident) patients. The results were interpreted as providing some support to the hypothesis that there is either a disruption in the integrity of the protein-lipid membranes of neurons or neuronal death resulting in reduced EEG microvolts. Associations were found between the locations of lesions and the EEG measures. While gray matter lesions were related to decreased microvolts on alpha and beta bandwidths, white matter lesions were associated with increased microvolts in the delta bandwidth. Gray matter atrophy in TBI cases has also been documented (Cohen, Inglese, Rusinek, Babb, Grossman, & Gonen, 2007). Neuropsychological deficits within this TBI group also were correlated positively with an increase in the delta microvolts, and negatively with a decrease in alpha and beta EEG amplitudes. These qEEG effects were not correlated with the interval of time between injury and MRI test nor with edema or acute injury effects, reflecting lack of spontaneous curing of the underlying physical problem (cross-sectional data). Thatcher was the first to indicate a lack of spontaneous cure in the TBI group (Thatcher et al., 1998). Thornton (2000) supported Thatcher's qEEG data and initiated the hypothesis that time does not heal in the TBI case.

Several measures of the changes in qEEG in TBI have been replicated in other studies. A discriminant analysis employing the qEEG variables to distinguish MTBI

from cerebral vascular accidents and normals showed 100% accuracy in separating TBI versus cerebral vascular accidents (Leon-Carrion, Martin-Rodriguez, Damas-Lopez, Martin, & Dominguez-Morales Mdel, 2008). The results with eyes-closed data indicated that the higher delta (1–3.5 Hz) microvolts were associated with lower the functionality measures (Functional Independence Measure) and Functional Assessment Measure). In addition the lower the beta (12–30 Hz) coherence values the lower the functionality measures. qEEG differences were reported between asymptomatic concussed athletes (89 days post-concussion) patients and control participants under the postural task conditions of standing up (J. Thompson, Sebastianelli, & Slobounov, 2005). Concussed athletes showed decreases in EEG microvolts in all frequencies under the standing condition when their eyes were closed.

One review of the research in the traumatic brain injury area indicated that numerous eyes-closed EEG and qEEG studies of severe head injury (GCS score of 4–8) and moderate injury (GCS score of 9–12) have agreed that increased theta and decreased alpha power (microvolts) and/or decreased coherence and symmetry deviations from normal groups often characterize such patients (J. R. Hughes & John, 1999). Changes in these measures provide the best predictors of long-term outcome. Other studies have reported that similar qEEG abnormalities are correlated with the numbers of bouts or knockouts in boxers (Ross, Cole, Thompson, & Kim, 1983) and with professional soccer players who frequently used their heads to affect the soccer ball's trajectory ("headers"; Tysvaer, Storli, & Bachen, 1989). The qEEG has also proven useful in discriminating between soldiers who experienced a blast injury and normals. The Thatcher discriminant function (Thatcher et al., 1989) correctly identified 88% of the soldiers with a blast injury history and 75% with no blast injury history (Trudeau et al., 1998).

There is additionally the problem of determining if the reductions in coherence or SCC values are the result of damage to the myelinated fibers (as indicated in DTI research) or damage to the gray matter, which is involved in the generation of the signal. In theory, the lowered coherence or SCC values could be attributable to either or both, as lowered coherence or SCC values could be due to lowered ability of the gray matter to generate a signal or transmit the signal to the white matter. However, the discussion that follows indicates that the gray matter still retains the ability to generate activity, as it is generating more beta activity than the normative group and is deficient in the SCC values. Whether the problem resides additionally in the gray matter's ability

to transmit the signal to the white matter is unresolved at this point. We delve into these distinctions and their respective values in more detail in the following discussion of the activation qEEG evaluation.

In conclusion, the research attests to the viability of the use of the qEEG in the determination of a TBI, along with other clinical information. It should be noted, however, that all of the research reported relationships were based upon eyes-closed data with the frequency range generally 21 Hz and lower. Although this line of research has proven productive in many clinical areas, there are inherent limitations to these types of data in two areas: (1) the limitation of the frequency range and (2) the inability to relate qEEG variables under task conditions directly to task performance.

Brief History of Field

Earlier studies of EEG biofeedback located the electrodes along the sensorimotor strip (see Figure 18.1, C3-Cz-C4) and employed a protocol that inhibited theta microvolts and augmented/rewarded beta (frequency range defined by authors) microvolts in a operant (rewarding of spontaneous behavior) EEG biofeedback session (Carmody, Radvanski, Wadhwani, Sabo, & Vergara, 2001; Linden, Habib, & Radojevic, 1996; Lubar, 1985; Othmer, Othmer, & Kaiser, 1999; Tansey, 1991; L. Thompson & Thompson, 1998). Positive clinical results of increases on IQ measures (average of 15 points across 4 studies; Linden et al., 1996; Othmer et al., 1999; Tansey, 1991; L. Thompson & Thompson, 1998), $+.50$ SD improvements in attentional abilities (Kaiser & Othmer, 2000), and a reduction in inattention as measured by the Test of Variables of Attention (Carmody et al., 2001) were documented. While the goal of this protocol is a reduction in theta microvolts and an increase in beat microvolts, the results of the training are not necessarily in that direction. For example, in a study conducted on site in an elementary school setting, children with the lowest initial microvolts of beta had significant increases over session, while those with the higher initial levels of beta show decreases in microvolts (Carmody, Quintela, Radvanski, Sabo, & Giorgi, 1999; Carmody et al., 2001). The differences in the findings of this study and that of others may be in the selection of subjects. Specifically, while the children in the Carmody studies were selected for ADHD based on the *DSM-IV* criteria, earlier studies selected children through the use of *DSM-III* criteria. The larger set of criteria used by *DSM-IV* may result in children who do not necessarily follow the “high-theta” and “low-beta” profile.

The next development in the field was the employment of eyes-closed databases, which could examine an

individual on a host of qEEG variables in comparison to an appropriate normative group. Protocol interventions were geared toward normalizing the qEEG. While normalizing theta and beta levels might seem to be a self-evident positive intervention, the normalizing of SCC and coherence and phase values is problematic. Under the assumption that coherence/SCC and phase values reflect white matter structure and functional ability, why would it be desirable to lower these values? In addition, in what frequency is it desirable to lower SCC or coherence values? The only way to answer these questions, and others, satisfactorily is to examine the brain under activation conditions and examine the correlations between cognitive success and the qEEG variables, thus the development of the activation qEEG evaluation. The employment of a higher frequency range in the activation database (32–64 Hz) has proven to be an important frequency, especially in the TBI situation (Thornton, 1999, 2000, 2003). In addition, the clarification of SCC values, which are negatively related to performance, was addressed with the finding that SCC theta generally is a negative correlate of effective cognition, especially in children under the age of 14. The SCC values in the higher frequencies (alpha to beta2) were usually related to more effective cognitive performance.

The Activation/Cognitive Challenge qEEG Evaluation

Pribram (2009) has commented that the “combination of recording EEG during problem solving behavior has led to and continues to lead to exciting breakthroughs in our understanding of the brain/behavior relationship.” In order to understand the nature of what is undertaken in the activation qEEG evaluation, the following description is provided. The preparation of the patient for the evaluation is the same as with obtaining eyes-closed data. The acquisition of data takes about 1 ½–2 hours, including preparing the patient and administering the tasks. The bandwidths are divided according to the following division: delta = 0–4 Hz, theta = 4–8 Hz, alpha = 8–13 Hz, beta1 = 13–32 Hz, beta2 = 32–64 Hz. The standard 10–20 system (linked ears reference) is employed.

The following is the sequence of task administration.

- (1) Baseline—A sample of 300 seconds of eyes-closed data for baseline purpose is obtained. This phase allows the participant to accommodate to the testing situation in addition to gathering data.

- (2) Auditory recall task—This task is conducted with eyes closed. The participant listens to four stories in sequence. After hearing the story the participant recalls the story silently for 40–50 seconds. The recording is then paused and the participant is asked to tell the examiner all the information the participant was able to recall during the quiet recall period.
- (3) Reading task—The participant is presented with one printed stories. They are asked to read the material quietly to themselves and reminded that they will be asked to recall the material. The recording lasts for 100 seconds. After the 100 seconds of reading, the participant is asked to close their eyes and silently recall for 50 seconds as much as they can about the story. After the quiet recall period, the recording is paused and the participant is asked to verbally recall as much as they can recall about the material that was just read.
- (4) Problem solving task—The participant is presented with the selected problems (series D and E) from the Raven's matrices. One of the items is employed as a sample to demonstrate the logic of the Raven's and discussed until the participant understands the purpose of the task. The participant then silently analyzes the problems and verbalizes his solution (providing a number). Due to the probability of increased artifacts in this task, data is collected for 400–500 epochs. This task also allows for a delay period with different cognitive activity intervening.
- (5) Delayed auditory recall task—The participant is asked to recall quietly for 60 seconds all of the stories that were read previously. Following the quiet recall period, the participant is asked to tell the examiner all of the information that was recalled during the quiet period.
- (6) Reading recall (delayed) task 5—The participant is asked, with eyes closed, to recall the story that they read. The participant is allowed 60 seconds of quiet recall time (eyes closed). The participant then informs the examiner out loud of all of the recall information.

After data collection, the artifacting process is applied to eliminate non-EEG signals in the data. The artifacting process involves visual inspection of each of the epochs and marking (via software) which epochs are affected by artifact (eye movements, muscle activity, etc.). The analyzed data is then run through analysis software that calculates means and *SDs* of the participant's response pattern across the nine cognitive tasks (not including eyes closed) on all the qEEG variables

available (microvolts, relative power, peak amplitudes, peak frequency, symmetry measures, SCC and phase). The software also averages the response pattern of the normative group across the nine cognitive activation tasks (excluding the eyes-closed task); this allows a comparison of the participant's overall response pattern to the overall normative response pattern. This type of analysis allows for the unique evaluation of consistent patterns of deficits in each task.

There are many measures of brain activity that are available from the qEEG. A specific location generates 18 values for the SCC value in a particular frequency. The 19 locations generate 171 SCC values for one frequency, and similarly for the phase values. When the five frequencies are combined for all locations across the phase and SCC values, the number of variables becomes 1710. To address the statistical problem resulting from these large numbers a flashlight metaphor is employed. We assume that each location is capable of generating a signal within a frequency range and that signal can be sent to every other location, thus reducing the statistical problem by a factor of eight. The concept of generator has been used (Schreckenberger et al., 2004) in the qEEG field and is thus a natural extension of the concept.

However, it should be noted that many theorists and empirical evidence point to subcortical locations as the possible origin of certain frequencies, notably the alpha rhythm originating from the thalamus. A mathematical technology called LORETA that, theoretically, enables specification of the location of the subcortical generator is currently being developed (Pascual-Marqui, 2002; Pascual-Marqui, Esslen, Kochi, & Lehmann, 2002). There are controversies concerning the ability of this technology, however, to fix accurately the origin of the signal. From a practical point of view the present 10–20 system combined with the high frequency activation database appears to be sufficient to obtain useful enough information to understand electrophysiological deficits and effectively direct rehabilitation efforts.

The Coordinated Allocation of Resources Model of Brain Functioning

Thornton and Carmody (2009a) proposed the coordinated allocation of resources (CAR) model of brain functioning. The model states that performance on any particular cognitive skill (auditory memory, reading memory, problem solving, etc.) is a function of the use of different electrophysiological variables (relative power, SCC, etc.) and locations. While different

cognitive skills may employ similar qEEG variables and locations as other skills, each skill operates differently than another skill. This model is somewhat implicit in fMRI and PET studies, which report location activation during cognitive tasks. A model of brain functioning that asserts not just what the brain does in response to a task but elucidates the necessary variables and their values or directions is a critical step in any theory of brain functioning. The CAR model is an initial attempt to provide the identification of these functions in terms of qEEG variables. In the case of MTBI it is a question of how the system is affected and what the effects are on the different cognitive tasks. If the CC is damaged in TBI cases, what does that mean for auditory or reading memory skills or what skill does it affect and to what degree? One method of answering the effect issue is to combine normals with a TBI group and correlate performance across the two groups with the qEEG variables. This was done in the case of auditory memory (Thornton, 2003) and the results will be discussed in this section.

The qEEG offers a viable technology for establishing the correlates of effective cognitive functioning as well as providing a rehabilitation method (Thornton & Carmody, 2009b). Most of the TBI research reports have employed an eyes-closed database. The research has shown that the TBI has elevated microvolt values in the lower frequencies (delta, theta) and decreased microvolt values in the upper frequencies (alpha, beta). These qEEG patterns have been assumed to be tied to cognitive problems in the TBI patient, as assessed during a different time period. In addition, problems in coherence in the TBI patient have also been documented in terms of increased frontal theta coherence, decreased frontal beta phase and increased left hemisphere beta coherence (Thatcher et al., 1989) and reduced beta SCCs (Thornton, 1999, 2000, 2003). The SCC and phase values are tied to white matter activity. The assumption is that lowered coherence/SCC and phase values reflect damage to the cortical-cortical white matter and/or the cortical-subcortical white matter (Destexhe, Contreras, & Steriade, 1998). While resting coherence and SCC values may be sensitive to white matter damage, a more demanding activation approach would more likely elicit where the weaknesses are in the white matter, which has been demonstrated in the Thornton (1999, 2000, 2003) studies.

The CAR model was built upon the idea that activation conditions are required for a thorough understanding of what is involved in the brain's electrophysiological functioning. The CAR model examines the qEEG variables on three levels: (1) what are the differences in qEEG

patterns between different brain states (Thornton & Carmody, 2008) such as auditory attention to listening to paragraphs; (2) what variables are being activated that relate to success at the task (Thornton, 2001) and (3) what are the relationship between task success and the absolute level of the specific qEEG variables that are positively and negatively correlated with success (Thornton, 2001). SPECT, fMRI and DTI studies (and others) have traditionally focused on identifying which variables are activated and then made the assumption that the activation relates to success at the task. While intuitively appealing, the assumption hasn't always been confirmed or examined. Thornton and Carmody (2008) investigated whether that assumption is valid in qEEG research by looking at the activation patterns of the different relevant conditions. For example, a participant engages in an auditory attention task (pen tapping on a table) and then an auditory memory task (listening to paragraphs). Success in the auditory memory task is related to specific qEEG variables (i.e., variables X, Y, Z). It would be a natural assumption that the participant would increase the values of the X, Y, Z variables from the auditory attention task. As an analogy an individual would engage certain muscle groups when lifting weights and other muscles when running, as each task requires activations of specific muscle groups to be successful. However, this is not what happens. The inefficiency hypothesis proposed by Thornton and Carmody (2009b) asserts that the normal (individuals with no history of learning disability, ADHD, psychiatric history) human brain does not increase the relevant qEEG values from the comparison condition (i.e., auditory attention vs. listening to paragraphs). For example, the coherence alpha relationships are critical to success in the listening to paragraph task yet the normal group does not increase these coherence alpha values from the auditory attention condition. Modern medical imaging technology needs to address this problem if the research results are to have relevance.

The CAR Model With Auditory and Reading Memory

The CAR model was developed on a number of cognitive skills (Thornton, 2001). We review two cognitive tasks—auditory memory for paragraphs and memory for reading material. Based on the results of a standard neuropsychological battery, only the logical memory subtest (paragraph recall) of the Wechsler Memory Scale-Revised predicted return to work at one year in a group of MTBI patients (Cifu et al., 1997). Based on this outcome, the logical memory (paragraph recall) was the task employed in the development of the activation

database. We present the effective qEEG response pattern in normal individuals for both auditory and reading memory and then examine one TBI individual's TBI response pattern for these tasks. The effective normal response pattern results have been previously published (Thornton, 2000, 2002). Figure 18.3 presents the correlates of effective auditory memory. The figure displays the reanalysis of the Thornton (2000) data with the flashlight metaphor. Circles with stars represent origin of the metaphorical flashlight beam of coherence alpha.

For auditory memory, in Thornton's (2001) normative sample of individuals (ages 14–70), these SCC alpha flashlights (F7, F8, C3, T3, P3) during the input stage (listening to paragraphs) are also the predictors during the subsequent recall period. The SCC alpha flashlights (F7, F8, C3, T3, P3) during the input stage of listening are predictors during of auditory memory the subsequent recall period in the normative sample. The predictors during the quiet recall stage are F7, F8, C3, T3, P3, and F4. The predictors for long-term recall (20 minutes later) remain the SCC alpha flashlights from T3, F7 and F8. Thus across three auditory recall tasks the SCC alpha relationships are the critical ones for success. Figure 18.4 presents an example of the effect of a TBI on SCC alpha relationships during the auditory input stage.

Stars represent the origin of the flashlight beam. Values in circles represent the differences of the subject from the normative database in standard deviations. The white circles represent values that are within .50 SD units of the normal mean (i.e., between $-.50$ SD and $+.50$ SD). The light gray enclosed circles represent values between $-.50$ SD and -1.50 SD. The darker gray enclosed circles represent values below -1.50 SD. The numbers in the circles show the SD value.

Figure 18.5 presents the qEEG correlates of reading memory. There was also a negative predictor from the

right posterior (T6-PB1). As the figure indicates the F7 flashlight SCC and phase activity in the beta frequencies (13–64 Hz) as well as T5 SCC alpha activity are the determinants of reading recall in a normal population.

Figure 18.6 represents the SD values for SCC and phase qEEG variables in a TBI participant during the reading task. As Figure 18.6 demonstrates, this TBI participant has significant deficits in SCC and phase beta2 values from the left frontal (F7) location. The star represents the origin of the flashlight. The light gray represents values between $-.50$ SD and -1.50 SD while the dark gray circles represent values below -1.50 SD. Stars represent origin of flashlight beam. Values in circles represent standard deviation difference of subject from normative database.

Figure 18.7 presents the flashlights of posterior origin for the same TBI participant. The SCC beta2 relationships have experienced significant deficits in functioning as a result of the TBI. The star represents the origin of the flashlight. The light gray represents values between $-.50$ SD and -1.50 SD while the dark gray circles represent values below -1.50 SD. Values in circles represent standard deviation difference of subject from normative database.

Intervention Rationale

In the CAR approach the selection of locations and protocols is determined by the results of the comparison of the patient's response pattern to Thornton's (2001) normative database for auditory input tasks (paragraph recall and auditory attention) and visual input tasks (reading, problem solving and visual attention). The total results are examined initially to localize weaknesses in the system. Then the individual tasks are examined, until a pattern of deficits becomes apparent. A specific task is approached first for treatment. The

From *NCLB Goals (and More) Are Attainable with Neurocognitive Approach* (Vol. 1), by K. Thornton, 2006, Charleston, SC: Booksurge.

Figure 18.4 TBI example: Auditory memory.

Figure 18.5 Correlates of reading in normal population.

first task addressed is usually auditory memory due to its importance in activities of daily life. When deficits are found in auditory memory, then the left temporal (T3) location is addressed first. The reasoning behind this decision resides in the PET and fMRI research data that indicate the importance of the left temporal lobe in auditory and verbal processing. A similar type of reasoning is applied to the selection of the protocols as the participant responds to the treatment and improves

their qEEG values. The SCC values are generally very responsive to the interventions. However, sometimes increases in SCC are difficult to obtain. In this situation, a different set of connection locations are selected.

Intervention Results

Most reviewers in the area of cognitive rehabilitation have not been encouraging of the approaches that have

Figure 18.6 TBI frontal response pattern: Reading.

Figure 18.7 TBI posterior response pattern: Reading.

been employed to date, due to lackluster research results (Thornton & Carmody, 2008). One study indicated there was no conclusive evidence for the efficacy of cognitive rehabilitation for children with acquired brain injury (Limond & Leeke, 2005). The Veteran's Administration concluded that there are no evidence-based clinical practice guidelines that address treatment of mild TBI. A report from the Rand Corporation emphasized the need to develop evidence based effective interventions for the cognitive problems of the TBI participant (Tanielian, Jaycox, Schell, Marshall, & Burnam, 2008). The evidence that follows will hopefully begin to change these opinions.

Employing the CAR model, the following EEG biofeedback intervention results have been reported with the LD/ADHD and TBI populations. Thornton and Carmody (2005) reported improvement in auditory memory function in a group of 20 LD/ADHD children that averaged 3 SDs for reading memory and 3.33 SD (or 296%) for auditory memory. Traditional tutoring methods with the LD/ADHD child average +.49 SD (Thornton, 2006) on the different measures employed by the respective

researchers. For example, the measures might assess comprehension, pronunciation, or vocabulary skills. Similarly, a group of 19 TBI patients improved auditory memory by an average of +2.61 SDs or 185 percent (Thornton & Carmody, 2008). In TBI intervention research, the cognitive rehabilitation methods using computers and strategies have low levels of improvement with an average of +.41 SD for paragraph recall. Thornton and Carmody (2008) employed SD effect size and confidence intervals to determine recommendation levels. The only recommendation obtained for the strategy and computer intervention approach was for word lists with computer interventions. Computers and strategies approaches obtained a 'not recommended' decision by the authors for paragraph recall, attention, and problem-solving skills. The only moderate recommendation obtained was for the activation qEEG approach to paragraph recall.

It is of some value to note that for both clinical groups (LD/ADHD and TBI) the EEG treatment group's performance at the end of the treatment was above that of the respective normative control group, a result that

could be considered a cure for the memory problems of these groups. For the LD/ADHD group, the initial mean was 8.4 ($SD = 5.5$) and the post mean was 21.8 ($SD = 6.6$). The comparison to the normative control group indicated that the treatment group was 1.53 SD above the control group at the end of the treatment. For the TBI group, the control group's mean average was 18 ($SD = 2.45$). The treatment group started at a mean of 8.6 ($SD = 4.31$) and ended at a mean of 24.5 ($SD = 7.25$) or 1.92 SD above the control group (employing means and SD of both groups). It would appear from these results with two different patient populations that EEG biofeedback intervention based upon an activation qEEG evaluation and guided by the CAR model is an effective intervention approach.

Specific Effects With TBI

The high frequency range (32–64 Hz) SCC effect of a TBI was originally reported in the Thornton (1999, 2000, 2003) studies that employed the high frequency activation database. The results indicated a specific deficit in the higher frequency (32–64 Hz) range in the SCC and phase relationships, under eyes closed, simple activation tasks, and paragraph recall tasks. These papers began to explicate what the connection between white matter damage and the qEEG variables might be under the assumption that the SCC values are determined by white matter functioning. The results for the TBI patient involved lower values in the SCC values of the beta2 frequency (32–64 Hz) for reasons biologically unclear at this point.

This discussion is relevant to the previously presented issue of children “growing into the deficit” caused by a TBI during youth. Thornton (2001) established that the predominant effective qEEG variable of children resides in relative power and microvolt levels of beta1 (13–32 Hz) and reduced relative power of theta. As the brain passes through adolescence and into adulthood these variables are no longer the dominant effective electrophysiological parameters during cognitive tasks. The predictors of cognitive effectiveness then predominantly reside in SCC and phase relationships. As these variables are the ones most affected by the TBI, the damage done to a young brain won't be apparent until early adolescence has passed and the need to employ SCC relationships becomes paramount. If, however, the damaged white matter connections have not spontaneously healed themselves then cognitive problems will become apparent, whereas previously they were not. Of particular relevance to this problem is the observation that “time does not heal” (Thornton, 2000). In the group of 32 mild to moderate TBI patients

the deficit pattern in the SCC and phase beta2 relationship was not a function of time since injury. In other words, the time distance between injury and assessment (cross sectional, not longitudinal data) had no effect on the deficit pattern. Thus, time did not result in spontaneous cure of the problem. This finding echoes those of previous reports (Lavoie et al., 2004; Rutgers et al., 2008; Thatcher et al., 1998).

The finding has significant implications for the field as it indicates that the presumed spontaneous cure does not find a correlate in the electrophysiology of the brain. Compensation then becomes the possible mechanism of return to normal functioning as determined by neuropsychological assessment. The Thornton (2003) study also indicated a change (compensation) in response functioning in the TBI patient as performance on auditory memory tasks was positively correlated with right temporal (T4) phase beta1 and left frontal (F7) phase beta2. In Thornton's (2001) normative sample auditory memory is partly determined by left temporal (T3) and left frontal (F7) SCC alpha (Figure 18.8).

Thus, there was a change to a higher frequency and a partial shift to the right hemisphere, characteristic of a compensatory mechanism. However it needs to be noted that the shift did not result in equal performance to the normal group. Thus the compensation pattern was ineffective in matching the performance of the normative group, a result contrary to other reported research in the area when simple tasks are employed. This result may be due to the high cognitive demands of free recall as well as the problems with high task demand tasks in the TBI patient. In fact, the performance of the TBI group was 1.28 SD below the normal group (employing means and SD of both groups) (TBI = 85, normal = 54) with an average of 3.2 years since time of accident. In addition, the Shipley Institute of Living Verbal IQ estimate for the TBI group was some 9 points below the normative group, while the education level difference was essentially the same (TBI-13.7 years of education; normative group 13.8 years of education). The nine point drop in IQ was also found with another TBI group using with the Wechsler Adult Intelligence Scale-Revised (Matarazzo & Herman, 1984). The abstraction scale of the Shipley revealed a seven point drop for the TBI group (Paulson & Lin, 1970). This particular group of TBI patients could be the 20% (or greater) who are hypothesized in the literature to experience significant and long lasting problems as a result of the TBI. There was a significant positive correlation between the Shipley verbal IQ measure (eyes closed) and time since accident (+.32) indicating some resolution over time of verbal abilities. However, neither the Shipley abstrac-

Figure 18.8 Stars represent origin of flashlight indicating the positive relations to total recall—within MTBI group.

Figure 18.9 Listening to paragraphs ($N = 85$). Arrows indicated decreased SCC values for TBI group at $p < .005$.

tion IQ measure nor the auditory memory score correlated positively with time since accident, indicating no spontaneous resolution of these problems.

The MTBI deficits do not affect SCC alpha flashlight activity to a significant degree. However, analyses of individual SCC alpha relationships do find significant deficits for the MTBI group when compared to the normative group. When the MTBI and normative group are combined and the relationships between qEEG variables and task success are examined, the deficit pattern

of SCC and phase beta2 relationships becomes predictive of success and failure on the task. The lowered SCC and phase beta2 relationships are negatively related to auditory memory performance, indicating that these variables are relevant to auditory memory (Thornton, 2002). As previously discussed, this type of data begins to answer how the deficits caused by a TBI affect specific abilities. In this example, the negative effect is on the normal predictors of auditory recall (SCC alpha relationships) and decreased SCC and phase beta2 relation-

ships. It has been hypothesized that this high frequency is intimately tied to memory processes (Lenz et al., 2008), reflecting a conceptual link to these findings.

Previously reported research with eyes-closed data (Leon-Carrion et al., 2008) had indicated deficit coherence beta (13–20 Hz) problems related to functioning problems. Thornton's eyes-closed data did reveal differences between the TBI ($N = 92$) and normative group ($N = 42$) in the occipital locations (O1-O2) with higher values for the TBI group on relative power of beta2, peak amplitude of alpha, but lower microvolts alpha, similar to the Thatcher et al. (1989) report. The O1 position analysis revealed lower values of delta (peak amplitude delta, lower microvolt delta) & higher peak frequency delta values. The O2 location showed lower values of peak amplitude of beta1 but higher values of beta (peak frequency of beta1 and beta2) while the right frontal locations (F8, F4, Fp2) showed higher values of peak frequency of beta2. The normal pattern of increased lower frequency (delta, theta) and decreased microvolts in the beta frequency range was not evident in our MTBI group, but were shown in previous reports in severe and moderate TBI (J. R. Hughes & John, 1999). In terms of SCC values the TBI group (eyes-closed data) had higher values of SCC theta flashlights from Fp1 and Fp2 while they had lower values of SCC alpha values from mostly frontal and central locations (F3, F4, C3, C4, P4, Fz, and Cz). SCC beta2 values were lower for the TBI group from the C3, T5, and Fz locations. Lower frontal phase alpha values were lower for the TBI group (Fp1, Fp2, F7, T3 locations) and lower phase beta2 values from frontal (Fz) location. The increase in SCC theta from Fp1 was similar to the Thatcher (1989) result. In summary, the TBI appeared to have higher beta activation levels at the occipital locations and right frontal locations with increased frontal SCC theta and reduced SCC and phase values from the alpha to beta2 frequency.

In the Thornton (2003) research reports the major problems were evident in the beta2 frequency range and most dramatically evident under the listening condition. Although the alpha SCC values were also negatively affected, the effect was much more frequent in the beta2 frequency and considerably more evident in the listening task. For example, under listening conditions, there were significant (p value set at .05) lowered values in the TBI group ($N = 79$) versus the normative group ($N = 45$) in flashlight SCC alpha values ($N = 2$), flashlight SCC beta2 (15), flashlight phase alpha (3), flashlight phase beta1 (3), flashlight phase beta2 ($N = 15$). However, individual analysis (non-flashlight) of SCC relationships revealed negative

effects in all the frequencies, however, involving SCC and phase (delta, theta, alpha, beta1) mostly emanating from frontal and temporal locations. This result is in line with previous reports of the effect of a TBI on frontal functioning.

qEEG Differences Between TBI and Normals During Auditory Memory Tasks

We present the main activation differences between the TBI group and normals as the groups engage in the listening, immediate recall and delayed recall conditions. It is a critical point to understand that none of the following relative power differences, which distinguish the TBI from the normal group, were evident under the commonly used eyes-closed condition while the SCC beta2 deficit pattern was evident, albeit less so than in the cognitive tasks. Thus the eyes-closed database reports that the clinicians may come across are problematic in the identification of a MTBI. Figure 18.9 presents the significant differences between the TBI and normative group during the listening task, with the p value set to .005. As can be seen in the figures the most prevalent results are the connection patterns across the hemispheres, implicating the role of the corpus callosum in the results. The figure also shows that the TBI group activated relative power of beta values in (right frontal relative power of beta2) frontal locations more than the normative group while decreasing relative power of delta values. This pattern was observed in the other measures of delta (peak amplitude, microvolt) in frontal and other locations. Perhaps this frontal beta is the measure that reflects the increased "effort" of the TBI group. However, it should also be repeated that the deficits in Figure 18.9 were at the .005 level and below. When the individual relationships are examined with respect to SD value differences, the homologous relationships generally (with some exceptions) had the greatest SD and raw score difference from Thornton's (2001) normative group, indicating that the major effect in the relationships displayed in Figure 18.9 were due to the CC effects, which are presented in Figure 18.10.

Figure 18.9 shows the breakdown of the homologous (similar locations in opposite hemisphere) relationships and reveals that the significant deficits (p value set at .05) involved these homologous locations (except O1-O2) in SCC beta2 and phase beta2 (Fp1-Fp2, F7-F8, T3-T4) values. As homologous locations are connected through the CC (Mildner, 2007), these results provide functional consistency with the

Figure 18.10 Relative power differences between TBI and normal in auditory memory task.

structural CC hypothesis evident in autopsy, DTI and other studies (Belanger et al., 2007; Taber et al., 2006; Wilde et al., 2008). In figure 18.10 the RDP indicates the relative power of Delta values lower for normals at $p < .005$, while RPB1 and RPB2 indicate the relative power of beta1 and beta2 greater in TBI group at $p < .05$.

Corpus Callosum Effects

Figure 18.11 presents the significant deficits in homologous relationships ($p = .05$) for the SCC beta (CB2) and phase beta2 (PB2) values. The only other significant homologous patterns (with respect to frequency) that emerged were the T3-T4 lower phase relationships (delta, theta, alpha, beta1) and Fp1-Fp2 (SCC and phase delta) for the TBI group. It is unclear why these particular locations and frequencies would be affected and not other homologous phase relationships.

The Thornton (2003) research report indicated that the relative power of beta1 values (12 locations of the 19 measured and involving five of the seven frontal locations) were negatively correlated with memory performance. A reasonable hypothesis would be that due to the damaged white matter in the TBI brain, the TBI patient activates beta activity (especially frontal) more than the normal group as a compensatory effort strategy, but this frontal activation is detrimental to the performance as memory performance, in adults, is predominantly an issue of SCC activity. The TBI group was lower than the normative group on 27 individual SCC alpha relationships; only two alpha relationships in the right hemisphere were negatively affected (F8-T4, F4-C4) and

only one centrally (Fz-Cz). The remaining 24 deficit SCC relationships involved left hemisphere locations. As left hemisphere SCC alpha relationships are the main correlates of auditory memory, these deficit values can explain the lowered memory performance in TBI. Thus, the deficit pattern begins to elucidate the relationship between the effect of a TBI (deficits in SCC beta2 and alpha values) on a specific cognitive task (auditory memory).

A similar pattern emerged for another auditory task (word list) both in terms of frontal beta activations and decreased values for the TBI group in the SCC and phase beta2 relationships (diffuse, but with greatest effects from frontal locations). The homologous location deficit was not as evident (although still significant) in this task for the TBI group.

In terms of activation levels from auditory attention, the TBI group increased beta1 relative power at the T4 location 9.6 points while the normative group decreased this beta1 relative power value 8 points, confirming a previous pattern noted of greater right hemisphere activation in the TBI group. In addition, an examination (Figure 18.9) of successful recall within the TBI group indicated there are positive correlations between T4 (phase beta1) and F7 (phase beta2) (Thornton, 2003). Thus the TBI group is increasing beta1 activity at a right hemisphere temporal location (T4) and increasing phase beta1 to obtain better memory scores while the normal subject is increasing coherence alpha from left hemisphere temporal locations (T3 and others) to obtain better memory scores. Thus the right hemisphere compensation argument appears to have some weight with these results as the TBI patient is employing the right hemisphere tem-

Figure 18.11 Homologous location SCC deficits in TBI group.

poral location (T4) to improve performance while the normal group employs the left temporal (T3).

In a visually oriented task, a similar pattern (albeit much weaker) was observed with respect to frontal beta activations and decreases in SCC and phase beta2 relationships from frontal locations. Of some interest to note, however, is that the frontal SCC and phase theta values were generally higher in the TBI group than the normative group. SCC theta values were negatively related to reading memory in the normative group. This type of analysis will begin to allow researchers to narrow in on the deficient patterns that need to be addressed in the rehabilitation interventions.

As Figure 18.12 indicates, during the immediate recall period the TBI values were similar to their relative values during the input stage, that is, lower levels of RPD (especially frontal), elevated levels of frontal beta (especially right frontal) and lowered levels of SCC alpha and beta2 as well as lower levels of phase beta2. The p value level was set to .05 for this analysis to display the broad effects on the SCC and phase beta2 relationships. If both the TBI and normative group are combined ($N = 114$) and the recall performance is correlated with the qEEG variables, then the results indicate several positive relationships between RPD in frontal loca-

tions (Fp2, F7, F8, F3, F4) and MD at Fp2 and F4 and memory scores. Negative relationships with memory scores were evident with all frontal beta1 relative power values, beta1 relative power at T3 & C3, frontal beta2 relative power values (Fp2, F7, F8, F3, F4), and peak amplitude and microvolt beta2 (F7, F8, F3, F4).

Positive relationships between recall performance and SCC beta2 were evident from frontal locations (F7, F8, F3, F4, and F3) phase beta2. In other words, what the TBI group was doing differently from the normative group (increased frontal beta activity, decreased frontal delta and decreased frontal SCC beta activity) was negatively related to success at recall. Within the TBI group ($N = 69$) the following delta variables were positively related to recall (RPD-F7, F3, F4, T3, T4) with negative relationships for beta (RPB1-F7, F3; T4—peak amplitude and microvolt beta1 and beta2; and T3—microvolt beta1). Thus, within the TBI the same pattern of decreased frontal delta and increased beta activity was negatively related to recall.

Figure 18.13 presents the differences during the long-term recall part of the task. The delay period was about 20 minutes after the initial task.

As Table 18.2 indicates in the delayed recall condition the TBI has higher activation levels of the frontal (especially right frontal) beta values but this time has

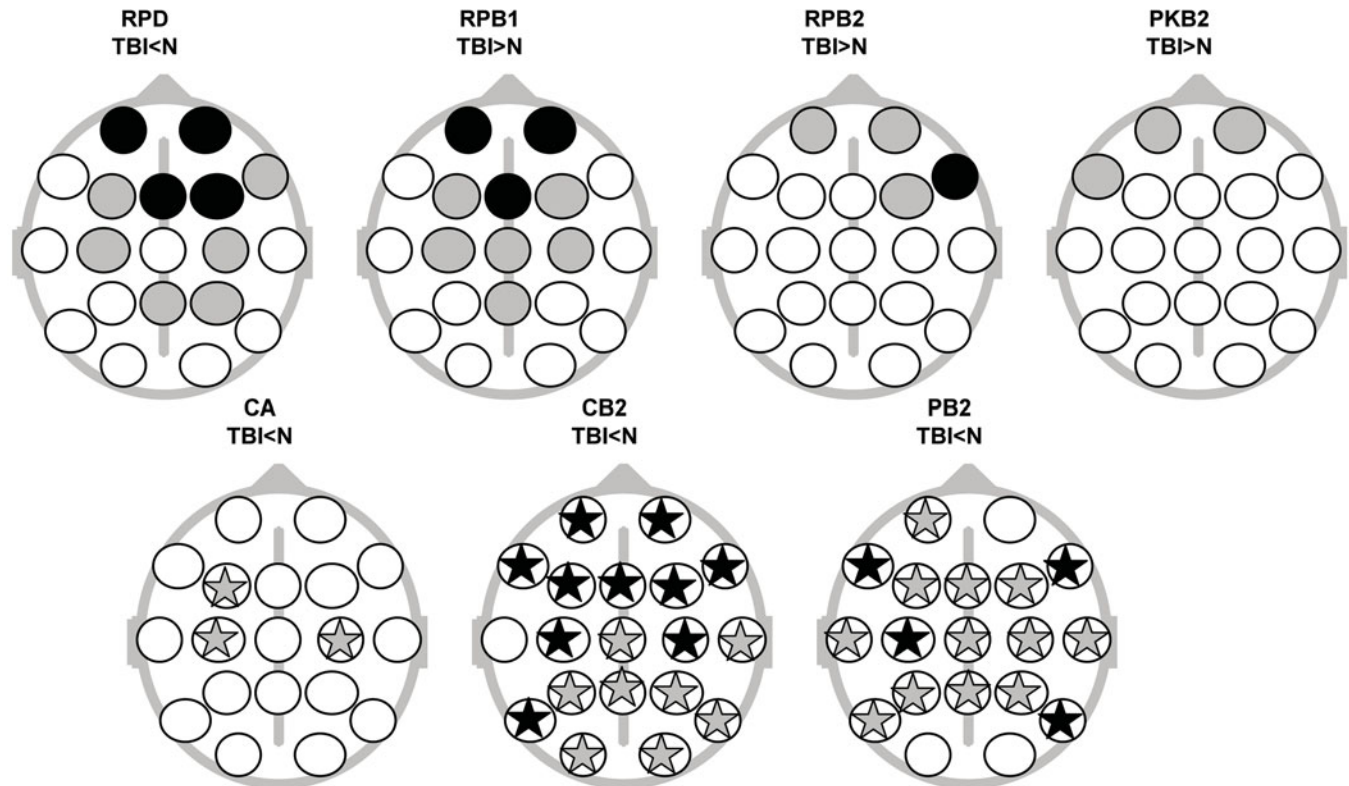

Figure 18.12 Immediate recall period: TBI versus normative group.

higher beta2 levels in all posterior locations as well as right hemisphere beta2 variables (relative power, peak frequency). Almost all of the TBI group's peak amplitude and microvolt delta values were below the normative levels (not visually presented). As left hemisphere (T3) SCC alpha relationships are positively related to successful delayed recall, there is a physiological "explanation" of the reasons for the TBI poor performance. The delayed recall condition shows a similar pattern of decreased frontal delta and increased frontal beta in the TBI group compared to the normative group but with the addition of greater posterior beta activation in the TBI group, which was unrelated to memory performance. This posterior beta activation pattern is similar to the findings of the Ricker et al. (2001) study, which found greater posterior rCBF (vs. controls) in the TBI group during free recall as well as greater right hemisphere activity and more dispersed activity (i.e., greater beta activations across diverse locations). In summary, the TBI patient's response pattern (vs. normals) is very similar across all three auditory memory tasks. The TBI patient decreases frontal delta, increases frontal and

right hemisphere beta activity and decreases SCC levels, all of which contribute to lower memory scores.

TBI Rehabilitation Examples

We provide some examples of how the qEEG activation evaluation allows for useful understanding of the cognitive deficits of the TBI patient and how the specific qEEG information allows for effective rehabilitation of the cognitive problems associated with a TBI. Some of the issues facing rehabilitation in this area have been successfully addressed with the activation qEEG database. These issues include the effect of age, multiple TBIs, structural lesions (such as hematomas) time since injury and surgical intervention in anatomically important locations for memory. Single-case studies have been documented that indicate the ability of the approach to be successful in all of these situations.

Case study 1 was a 69-year-old female who had suffered a left frontal hematoma as a result of an

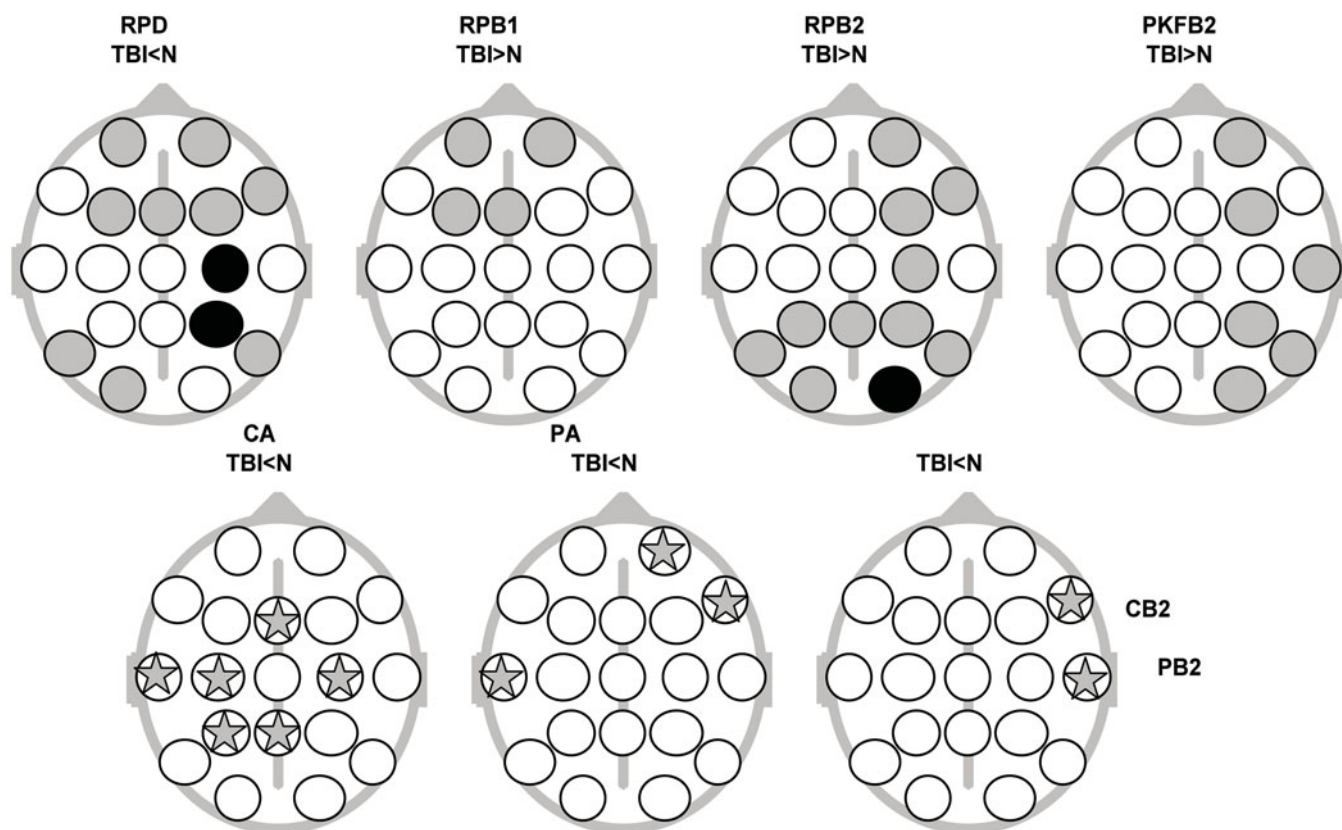

Figure 18.13 Delayed recall differences between TBI and normal group.

MVA. She was in a coma for several months. She entered treatment 2 years after the MVA. At the onset of the interventions she was able to recall 9.75 pieces of information from the paragraph recall task (immediate and delayed recall) and by the end of treatment she was recalling 32.5 pieces of information. A piece of information is a section of text that expresses an idea. For example, in a story that starts with “John Smith / went to the grocery store / on a Saturday” there are 3 pieces of information that are separated by the forward slashes. The interventions focused on the phase and SCC relationships between Fp1 and F3 and Fp1 and T3, which showed significant deficits, presumably caused by the left frontal hematoma. She was able to substantially improve the values of the variables affected (Fp1-F3 phase beta2—from 35 to 70; Fp1-T3 phase alpha—from 52 to 66).

In case 2, the 34-year-old male patient underwent stereotaxic surgical removal of portions of his left anterior temporal lobe, hippocampus and amygdala for seizures. He started with a total base memory of 11 and

was obtaining a total recall score of 19 by the end of the treatment. In case 3, the 48-year-old had experienced a TBI some 15 years prior to the evaluation. The patient’s initial recall score was 11.5 and by the end of the treatment he was obtaining a score of 31. A one year follow up assessment revealed that his memory had continued to improve as he obtained a score of 37.5. In case 4, there was a history of multiple mild head injuries as the patient was a 40-year-old stunt actress. The average SCC beta2 value from the right frontal location (F8) to the left posterior locations (T5, P3, O1) was 52. After 40 sessions she had improved this value to 74 (normative group is 70) or 6.32 *SD* units. Her auditory memory improved from 16 to 37.5 and her reading memory improved from 25 to 43.

While it is important to demonstrate improvement on neuropsychological memory measures, it is also relevant to demonstrate that there are relevant changes in the qEEG values. In case 5, the individual was involved in a serious MVA during which his car flipped over twice resulting in the roof being caved in. The posterior and superior sections of his head impacted on different

structures of the car. He felt dazed, dizzy, had a “huge” bump on his head, and was in ICU for 5 days. Table 18.3 shows the initial Z score difference from the normative control group, the Z score difference following the treatment and the total Z score change. The values represent the average values across all 9 cognitive tasks involved in the evaluation (not including the eyes-closed condition). In the initial evaluation, the patient’s qEEG pattern showed excessive delta activity at T5 and P3. Treatment interventions were focused on this problem with the resultant changes shown in Table 18.3. The table presents the relative power values for the different frequencies in the left and right frontal and posterior locations, where the greatest changes occurred.

Of some interest to note is the increased beta activity in the left frontal versus right frontal as well as left posterior versus right posterior. In both left hemisphere quadrants there was a greater decrease in delta and greater increase in beta activity. Table 18.4 presents the SCC beta changes at these respective locations.

As Table 18.3 indicates there was significant improvement in SCC beta activity. Overall (across all locations) delta SCC values increased .24 *SD*, theta SCC values increased .72 *SD*, alpha SCC values increased .47 *SD*, beta1 SCC values increased 1.29 and SCC beta2 values increased an average of 1.19 *SD*.

The cognitive changes included the following: a decrease in errors on the Category test (77 to 56), Shipley IQ increase (99 to 113), improved total recall score on the CVLT (43 to 53) or standard score increase (25 to 41), decreased time (10 minutes to 7 minutes) and errors (13 to 5) on a visual scanning test developed by Thornton, improvement in paragraph recall raw score value (22 to 36), improvement in raw reading recall scores from 5.5 to 18, no significant change on the CALCAP reaction time test or Michigan Serial recall test of working memory, and poorer performance on the Wisconsin Card Sorting Test. The CALCAP reaction time test is a series of 10 tasks requiring rapid responses (tapping a spacebar) based upon conceptual rules provided to the patient by the software. The focus of the treatment was on auditory recall.

In specific improvements in SCC alpha were obtained under the auditory recall condition. The *SD* change (post vs. pre) from the normative reference group averaged .72 *SD* across all locations and .69 *SD* on the five predictors of auditory recall in Thornton’s (2001) normative sample (T3, F7, C3, F8, P3). The total SCC alpha relationships in the initial evaluation were -1.04 *SD* below the normative group and -.18 *SD* below normative group upon reevaluation. This change indicates that the intervention can return the TBI

individual to the normal effective response pattern and thus improve the underlying electrophysiological deficit involved. This is the first line of evidence that the cognitive deficit in TBI can be returned to normal functioning both on a performance level as well as the electrophysiological level.

The conclusion from this above detailed analysis is that rehabilitation EEG biofeedback protocols need to be individualized, can be meaningfully related to specific cognitive skills, can be effectively addressed with EEG biofeedback employing the CAR model, can effectively address physical damage caused by a TBI, can obtain generalization of effects both in terms of cognitive abilities and qEEG variables, and can obtain significantly better results than presently employed methods in the fields of rehabilitation of the learning disabled child and traumatic brain injured adult.

CONCLUSION AND RECOMMENDATIONS

The DTI, ERP, and qEEG approaches to the understanding the diagnostic issues of TBI appear to be the most productive. In providing useful rehabilitation information the qEEG appears to be the instrument of choice. Modern medical imaging technology has brought us forward with a better understanding (albeit still incomplete) of what occurs in TBI. Rehabilitation efforts have been extremely limited in their effectiveness and lacking a sound empirical basis. The activation quantitative EEG offers a possible improved conceptual and empiri-

cal foundation to our understanding and rehabilitation efforts. The research results for qEEG interventions for auditory memory appear to be adequate for the TBI patients at the present time.

Personality Disorders

Maria Poston
Kara Liebling Kahan
Dawnelle Schatte

CONCEPTS AND DEFINITIONS

When clinicians begin their training, there is nothing more confusing and frightening than facing the patient with borderline personality disorder (BPD). I have even heard of jaded biologically based psychiatrists teaching students that diagnostically, “those patients are the ones we don’t like.” Historically, these patients were thought of as the “stably unstable,” for whom there was little hope for anything other than chronic illness (Gabbard, 2007). This may be driven by the clinician’s fear of his or her own inability to help these patients, or the clinician’s own hopelessness about the condition. Yet this, and all personality disorders, is a disorder with evidence-based support for improvement with pharmacological and psychotherapeutic approaches. In order for a clinician to effectively treat such patients, he or she must have compassion for the patient based in an understanding of the developmental traumas and familial predispositions that contribute to this state. In particular, it is important to understand how as a child this patient may have felt invalidated and never given a voice for expression. The therapist should have an understanding of the neurobiological and behavioral entrenchment that counteracts the therapeutic approach. The therapist should also understand the chronic, demanding, and draining nature of engaging these patients, so that he or she can keep perspective on asking for support when needed, and not

basing his or her own self worth as a therapist on the patient’s day-to-day improvement. The clinician should hold out hope that things can improve and go on to lend that hope to the patients.

The diagnostic criteria for personality disorders (PDs) were first printed in the *DSM-III* of the American Psychiatric Association in 1980, when the multiaxial diagnostic system (including Axis II for PDs) was introduced. Individuals with personality disorders possess long-standing maladaptive traits that contribute to their personal distress and impair their ability to effectively function in various realms—cognition/reality appraisal, affectivity, interpersonal functioning, and impulse control. The *DSM-IV-TR* (American Psychiatric Association, 2000) describes these dysfunctional patterns of relating to oneself and the world as not only enduring but also pervasive and inflexible. By itself, this general description provides us with a glimpse of the serious nature and extent of affliction of those with personality disorders.

Lenzenweger, Lane, Loranger, and Kessler (2007) reported the first nationally representative estimates of personality disorders based on clinical interviews as a part of the National Comorbidity Survey Replication. The prevalence estimates were 5.7% for Cluster A disorders, 1.5% for Cluster B disorders, 6.0% for Cluster C disorders, and 9.1% for any personality disorders. The only specific disorders they evaluated in their

largest sample were BPD, with a prevalence estimate of 1.4%, and antisocial PD, with a prevalence estimate of 0.6%. Antisocial PD is more prevalent among men than women. A diagnosis of Cluster B disorders is inversely related to age and education, and positively correlated with unemployment. Lenzenweger et al. note this sample may have relatively fewer persons with Cluster B disorders because clinical samples gathered by other researchers have been done in younger populations than Lenzenweger et al.'s community sample.

There are high rates of comorbidities of other *DSM-IV* disorders among people with personality disorders, further complicating care and adding to the burden of disease. The co-occurrence of PDs is as common as the occurrence of PDs (Lenzenweger et al., 2007). They found that comorbidities with Axis I disorders are much higher for Cluster B (84.5% of cases with BPD meet criteria for at least one Axis I disorder in the past 12 months) than Clusters A or C, although large portions of all people with PDs also meet criteria for Axis I disorders. For example, one study of patients with panic disorder found 54% met criteria for paranoid personality disorder (Reich & Braginsky, 1994, cited in Gabbard, 2000b, p. 386). In Lenzenweger et al.'s (2007) community sample, they found the degree of functional impairment (based on World Health Organization Disability Assessment Schedule areas of basic and instrumental role functioning) was associated with comorbid Axis I disorder. The presence of a PD had the strongest association with impairment in social role functioning.

Persons with PDs are high utilizers of care, with 39% receiving some type of treatment for mental health or substance use each year (Lenzenweger et al., 2007). More people with Cluster B (49.1%) than Cluster A (25%) or Cluster C (29%) seek care. Persons with PDs are nearly as likely to seek care from general medical providers (19%) as from mental health professionals (22.8%) and, of mental health professionals, are nearly as likely to seek help from psychiatrists (14.3%) as from other professionals (17.3%). It may be the higher percentage of persons with Cluster B disorders seeking care or the higher severity of target symptoms that makes Cluster B appear to have a higher prevalence than the other PDs to clinicians. For example, the prevalence of BPD in the general population is estimated to be between 2% and 4%, but the prevalence in clinical populations is closer to 15%–25% (Gabbard, 2000b, pp. 416–417). Bender et al. (2001) compared treatment utilization of patients with different and severe forms of personality disorders (schizotypal, borderline, avoidant, and obsessive-compulsive) to those with major depressive disorder without an Axis II diagnosis and found

greater consumption of psychological/psychiatric treatment by those with personality disorders than the latter comparison group. More of the patients with personality disorders (96%) had received some form of outpatient psychotherapy than the patients with depression (85%). In addition, 81% of the PD patients received psychotropic medication during their lifetimes, compared to 64% of the depressed group. That same study also showed that patients with obsessive-compulsive personality disorder (OCPD) were nearly 3 times more likely to have received individual psychotherapy than the depressed comparison group, and patients with BPD received significantly greater amounts of nearly all types of psychosocial treatments (i.e., individual psychotherapy, group psychotherapy, day treatment, psychiatric hospitalizations) than the depressed group and the other personality disorder groups. Relative to the depressed comparison group, BPD patients were also twice as likely to have used antianxiety and anti-depression medication, 6 times as likely to have used mood stabilizers, and 10 times as likely to have been prescribed antipsychotic medication.

Longitudinal comparison of the effects of physical illness, Axis I mental disorders, and PDs from age 16 years to 33 years (Chen, Cohen, Kasen, Johnson, Berenson, & Gordon, 2006) shows that there are long-lasting effects on quality of life for these people. The presence of an Axis I disorder in adolescence affects the quality-of-life domain for social relationships and physical health in adulthood, but the presence of a PD affects quality-of-life domains of social relationships, psychological well-being, role function, environmental context, and physical health. The physical health problems most highly associated with the mental disorders were musculoskeletal disorders (orthopedic problems or chronic pain) at 44.2%, and neurological disorders (migraine or other chronic headaches or epilepsy or other neurological problems) at 42.4%. This suggests the importance of dealing with all realms of a patient's functioning in treatment. With the stigmatization of mental illness, many patients may chose to get their care from non-psychologically trained medical professionals, who have variable amounts of training in and innate interest in psychodynamic issues. It also means there may need to be many professionals working with the same patient to address all the physical and mental health issues.

The cost of personality disorders does not just affect the person or his or her closest friends and family. Soeteman, Hakkaart-van Roijen, Verheul, and Busschbach (2008) found that the economic burden of personality disorders is comparable to that of schizophrenia and

much higher than that of other disorders like depression and anxiety. In their sample of treatment-seeking individuals, the direct medical costs (66.5%) exceeded the indirect costs of productivity losses. This study estimated the overall cost per patient with PD as nearly \$15,000 per year.

CLINICAL ASSESSMENT AND DIAGNOSIS

Psychological assessments are valuable components of the evaluation and treatment process of those with personality disorders. The extensive use of personality tests has increased since the First World War and has broadened beyond the scope of a mere screening tool for military recruitment. Psychological testing aids in answering specific questions about a patient and assists the clinician in making relevant decisions regarding how to provide psychiatric treatment and psychological interventions. More specifically, psychological assessments provide clarification of a patient's presenting problem and the interaction of current symptoms; help to rule out or differentiating between possible diagnoses; identify internal and external regulatory mechanisms, and elucidate personality, social, and cognitive functioning. The success that psychological evaluations have in answering specific questions, in part, depends on the ability of the administrator to clearly convey to the patient its purpose and potential benefits and on the ability to obtain the patient's trust, consent, and cooperation. Procedures that inquire into many domains of the patient's life can be perceived as intrusive or even threatening, particularly by those with personality disorders, and can influence their attitudes and motivation during the evaluation process. In addition to interviewing and testing the patient, treatment team members can also gather relevant psychological/psychiatric information from past records and from the patient's family members; friends; and, in the case of adolescents, teachers. Obtaining information about the patient from various sources provides a more comprehensive view of the patient's functioning and thus promotes efficacious treatment planning.

The psychological assessment begins with the clinical interview and then proceeds with an assortment of measures, such as objective personality inventories, projective personality tests, intelligence tests, achievement tests, and neuropsychological tests, depending on the nature of the referral question. The clinical interview is the initial method of gathering relevant background and psychological information. Interviews can be structured or semi-structured. Structured interviews

promote standardization across interviews, as they contain a set of predetermined questions from which the interviewer must not deviate. Standardization not only increases reliability among diagnosticians but also allows for trained nonprofessionals to conduct interviews, as is done in research investigations. Commonly used clinical interviews include the Diagnostic Interview for *DSM-IV* Personality Disorders (Zanarini, Frankenberg, Sickel, & Young, 1996), the International Personality Disorder Examination (Loranger et al., 1994), the Structured Interview for *DSM* Personality-IV (Pfohl, Blum, & Zimmerman, 1997), and the Structured Clinical Interview for *DSM-IV* Axis II Personality Disorder (First, Gibbon, Spitzer, Williams, & Benjamin, 1997). Semi-structured interviews allow the treatment team greater flexibility in pursuing various lines of questioning. Because of its flexibility, it relies on professional experience to recognize which trend of additional querying is indicated.

Personality functioning can be assessed by objective and projective measures. These types of tests differ in their structure, administration, and the kind of information elicited. Objective measures are empirically derived, are commonly self-report inventories, and are administered in a paper-and-pencil format. Patients are presented with a number of statements or descriptions, and they are instructed to answer true or false or yes or no or to choose from a list of responses. Examples of commonly used objective personality measures include the Minnesota Multiphasic Personality Inventory (Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989), the Millon Clinical Multiaxial Inventory (Millon, 1997; Millon, Millon, & Davis, 1994), and the Personality Assessment Inventory (Morey, 1991).

The MMPI was originally developed in 1940 by Hathaway and McKinley as a diagnostic tool for detecting various aspects of psychopathology. Unlike personality inventories that were developed through a logical keying approach, in which items were chosen based on their face validity, the MMPI was generated through the use of an empirical keying approach (Graham, 2006), an atheoretical method that selects items based on their ability to discriminate between groups of individuals with certain diagnoses. The original MMPI consisted of 10 clinical scales that screen for somatic complaints, depression, social maladjustment, antisocial behaviors, gender identification, paranoid ideation, anxiety, obsessive thoughts, schizophrenia, and hypomanic symptoms, and 4 validity indicators (i.e., cannot say, lie, infrequency, and correction). Revised and restandardized, the MMPI-2 includes additional validity, content, and supplementary scales. It currently has 567 items

and takes 1–2 hours to complete. To interpret a patient's profile, elevated clinical scales are combined to form 2- or 3-point code types, which are associated with certain personality features, symptoms, and diagnoses and allow for inferences regarding behavioral patterns. The MMPI-2 is stronger in differentiating between Axis I diagnoses than it is with Axis II.

The MCMI is an instrument that is widely used for identifying specific personality disorders. The MCMI-III, the current edition, contains 175 items and takes approximately 25 minutes to complete. It requires a basic eighth-grade reading level. The measure contains 28 scales, which are grouped into five categories, namely, modifying indices, clinical personality patterns, severe personality pathology, clinical syndromes, and severe syndromes. Such organization, which concurrently identifies characterological patterns along with clinical syndromes, is intended to correspond to the multiaxial model of the *DSM* and aids with integrating information regarding trait structure, relational patterns, and symptoms in the interpretive process. Scores between 75 and 84 suggest the presence of a pattern, pathology, or syndrome, while a score of 85 and above provides a more accurate indication of its prominence. In contrast to the MMPI, which possesses high validity in diagnosing Axis I disorders, the MCMI has low validity in that domain but is strong in differentiating between Axis II conditions.

The PAI is another self-report inventory of personality. It consists of 344 items and yields 4 validity scales, 11 clinical scales, 5 treatment scales, and 2 interpersonal scales. This instrument, which requires a minimum of a fourth-grade reading level, takes approximately 40–50 minutes to complete. Because it only assesses two personality disorder features (i.e., borderline and antisocial), it is limited in its ability to capture a broader spectrum of character pathology, unlike the MCMI. Its use of a 4-point Likert scale adds dimensional features.

In contrast to objective tests, which avail the test taker more opportunities to consciously organize his or her responses according to social expectations, proprieties, or restraints, projective tests engage the patient more freely and provide access to his or her inner world, problem-solving style, internal conflict, desires, fears, needs, motivations, affective tendencies, interpersonal patterns, and any other aspect of the inner experience that may not be readily conscious and that influences their behavior. This is a more uninhibited approach to assessing personality structure. During administration of projective tests, patients are asked to either describe what they perceive on stimulus cards, create a story based on scenes, or draw pictures. The Rorschach Ink-

blot Test and the Thematic Apperception Test are the most prominent projective measures. The Rorschach is composed of 10 cards on which are bilaterally symmetrical ink blots. The Rorschach is predicated on the basic premise that one's regulatory and organizational processes affect one's responses to environmental stimuli, and when one is introduced to vague situations or ambiguous stimuli, reliance on those internal processes intensifies. An examinee must then depend on residual internal resources to construct meaning from his or her perceptual experience. Thus, an examinee's constructive patterns and responses on the Rorschach are indicative of his or her approach to ambiguous situations. Responses are recorded verbatim and scored based on descriptions of location, determinants, and content. The Thematic Apperception Test consists of a series of pictures, some of which are slightly ambiguous. The examinee is asked to create a story based on the picture scenes and to include elements such as what is happening in the picture, what led up to the event, how are the characters thinking or feeling, and how the story will end. As in the Rorschach, a core assumption of the Thematic Apperception Test is that examinees will project onto the pictures their patterns of relating to their environment and subsequently will reveal the important aspects of their personality structure and psychological functioning. Examiners look for themes, main heroes, descriptions of the environment, conflicts, needs, relationship patterns, affective quality, defense styles, and ego/superego structures.

THEORETICAL BASIS: NEUROPHYSIOLOGICAL

The American Psychiatric Association labeled the 1990s "The Decade of the Brain" for psychiatry. As a field, we are working to integrate and grow what we know about the brain along with what we know and are learning about the mind. It is an exciting time as genetic and neuroimaging studies are used to inform us about the disease process and prove or predict therapies. The next edition of the manual for psychiatry, the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-V)*, due around 2012, will likely incorporate these scientific developments. Thus the definition of personality disorders is evolving to include evidence-based methods. The planning committees have been working since 1999 to determine what information is available to inform classification and to promote further discussion and research to make those decisions. The diverse areas of interest to be included are twin studies,

molecular genetics, neuroscience, cognitive and behavioral science, development, disability, and cross-cultural awareness (<http://www.psych.org>).

As we examine the neurophysiological basis of personality disorders, there is a variety of factors to consider when reviewing the literature. The diagnostic standards for the personality disorders are spelled out in the *DSM-IV* and can be simplified as maladaptive patterns of behavior in four domains: cognition, affect, impulsivity, and interpersonal relations (McCloskey, Phan, & Coccaro, 2005). There is currently no model that explains all the data we have, and many experiments offer contradictory results. Studies are done based on current (and even past) *DSM* criteria for disorders, a nomenclature that has been called into question as the American Psychiatric Association considers a new classification. Many studies are done on personality traits, like impulsivity or novelty seeking, and should be considered even if they don't fit a neat subset of a specific personality disorder. It is rare to find a study that measures functional neuroimaging, molecular genetics, and neurochemistry in the same subjects. Adding to the complexity is the fact that brain function does not appear to be linked to a single neuron or neurochemical, but instead interaction and modulation contribute to the vicissitudes of this area of study (Paris, 2005).

It is important to develop a model of personality functioning, both adaptive or non-pathological and maladaptive or pathological, because it is from that model that we develop testable hypotheses. From an evolutionary model, there seem to be primary traits that may have evolved to solve adaptive problems presented in the environment of our ancestors. Primary traits seem to be genetically predisposed, and those genes also encode processes that influence what we pay attention to in our environment (Livesley, 2008). The environment then influences the biological factors created by the genes. Both genes and the environment affect the neuropathways (the hardwired anatomy and the neurotransmitters) that are ultimately responsible for normal functioning and maladaptive disorders. The imaging and genetic information to follow is still in the research stages and is used to test and refine models of personality. This is not for diagnostic testing, as there are no imaging or laboratory studies for personality disorders.

NEUROBIOLOGY OF PERSONALITY FUNCTIONING

The neuroimaging data used as evidence for these models is often contradictory. Several reasons for this

have been hypothesized, including drugs in the person's system; comorbid psychiatric disorders; different resolutions of images or laboratory conditions; estrogen levels, which can influence cerebral perfusion; heterogeneity in people with the disorder (Lis, Greenfield, Henry, Guile, & Dougherty, 2007); inadequate normative data and sample sizes; imprecise definitions of meaningful group differences; poor replicability between centers; difficulties with automated methods to study large populations; and age-related developmental differences (Hendren DeBacker, & Pandina, 2000). With personality disorders, it is questionable if the current categorical definition is adequate to define specific group differences, since these disorders may merge imperceptibly into normal variants and into each other (*DSM-IV-TR*, cited in Widiger & Mullins-Sweatt, 2005, p. 35). Thus the current data should be considered preliminary and for research purposes only.

There are four domains of symptoms in the *DSM-IV* that define most disorders, including personality disorders. These are cognition, affect, impulsivity, and interpersonal relations. The major challenge in understanding human behavior is characterizing the interplay of cognition and emotion (McCloskey et al., 2005). In order to understand the biological basis of personality function and disorders, we can look at the general areas thought to be responsible for these actions, and the functions of the circuits that connect them. These generalized conclusions of functional areas have come from animal models, studies of persons with accidental damage to these areas, and functional neuroimaging of specific tasks. The anatomical areas of interest for this discussion of cognition and emotional processes have been included in Table 19.1.

The frontal cortex is most responsible for the cognitive control and planning of movements (the premotor area), thought, executive functions, working memory (the prefrontal area); extinction of conditioned responses or relearning, experiential emotion, recognition of the self and others, planning (medial prefrontal cortex), executive functions (dorsal frontal), and cognitive-related inhibition of automatic emotional responding (anterior cingulate cortex; Nahas, Molnar, & George, 2005). Executive functions can be defined as the higher-order thought process of motivation, planning, regulating, and controlling behaviors (Capruso & Levin, 1995, p. 219). A representation of a "goal state" in working memory is thought to be implemented in the dorsolateral prefrontal cortex (R.J. Davidson, 2004, p.1066). It can be thought of as the area that performs ego functions such as impulse control and affect regulation. In addition, it can be thought of as the area that maintains

19.1

Cognitive and Emotional Anatomical Areas of Interest

COGNITION

Cognitive control of behavior

Executive function

Working memory

Attention and impulse control

Areas implicated in cognition:

Medial prefrontal cortex

Dorsolateral prefrontal cortex

Anterior cingulate cortex

Function of areas:

Self-directedness, object recognition, movement, planning

Working memory, planning, representation of goal state

Cognitive related inhibition of automatic emotional responding

EMOTION

Emotional processing

Affective processing

Social-interpersonal cognitions

Areas implicated in emotion:

Insula

Orbitofrontal cortex

Medial prefrontal cortex

Hippocampus

Superior temporal sulcus

Septum

Amygdala

Thalamus

Hypothalamus

Function of areas:

Novelty seeking

Cooperativeness, empathy

Experiential emotion

Explicit memory and learning

Assessment of the relevance of external Events to the self

Regulate sexuality and preservation of safety
(anticipatory anxiety)Feeding and aggression vs. satiety and satisfaction;
appraisal of hedonic value or novelty

Relay sensory information to cortex

Modulate autonomic nervous system and endocrine

From "Functional Neuroanatomy and Brain Imaging of Personality and Its Disorders," by C. R. Cloninger, 2002, in H. D'haenen, J. A. den Boer, & P. Willner (Eds.), *Biological Psychiatry* (pp. 1377–1385). West Sussex, England: John Wiley & Sons, Ltd; "Neuroimaging and Personality Disorders," by M. S. McClosky, K. L. Phan, and E. F. Coccaro, 2005, *Current Psychiatry Reports*, 7, 65–72; and "Brain Imaging," by Z. Nahas, C. Molnar, and M. S. George, 2005, in J. S. Oldham, A. E. Skodol, and D. S. Bender (Eds.), *The American Psychiatric Publishing Textbook of Personality Disorders* (pp. 623–639). Washington DC: American Psychiatric Publishing.

self- and object representations. From an evolutionary perspective, it is our most highly evolved and developed part—the part that makes us the most human. Thus it has been highly studied from deficit injury states and normal functional neuroimaging in order to help us understand personality disorders.

The limbic and paralimbic brain regions most likely are responsible for emotional and affective processing and social-interpersonal conditioning (McCloskey et al., 2005). These are ancient structures that play an important role in survival by modulating memory (especially the hippocampal formation), emotions and drives (especially the amygdala), homeostatic functions and neuroendocrine control (especially the hypothalamus), and olfaction. This region is composed of the limbic cortex (parahippocampal and cingulate gyri, medial orbitofrontal cortex), hippocampal formation, amygdala, olfactory cortex, thalamus and hypothalamus, septal nuclei, and basal ganglia (Blumenfeld, 2002, p. 762). The medial orbitofrontal cortex (structurally part of the frontal cortex discussed above) is part of the limbic association cortex for reward, thought, cognition, movement, and planning. The hippocampus is responsible for explicit memory and learning. The amygdala is responsible for appraisal of hedonic value and novelty of stimuli and controlling physiological response to stimuli. The thalamus is the major relay site for sensory information to the cerebral cortex. The hypothalamus modulates autonomic nervous system and endocrine activity (Nahas et al., 2005, p. 626). It integrates input from the limbic areas to regulate the tonic opposition of the two branches of the autonomic nervous system, sympathetic and parasympathetic, to maintain homeostasis. The parasympathetic functions are sexual arousal, feeding, digestion, and sleep; the sympathetic functions are sexual orgasm, preparation for fight or flight, and wakefulness (Cloninger, 2002, p. 1379). The basal ganglia are composed of the input area of ventral striatum (nucleus accumbens, ventral caudate and putamen) and output area of ventral pallidum (projects to thalamus in striato-thalamic circuits). The septal region is near the basal forebrain. It contains the medial septal nuclei, which contain cholinergic nuclei projecting to the hippocampal formation (Blumenfeld, 2002, p. 768).

In addition to the simplification of functions of the above anatomical areas, the connections between these areas are important for understanding functions. By convention, the circuits are named by the areas they start from and project through and to. The septo-hippocampal-hypothalamic connections are needed to inhibit behavior to preserve safety and thus passive-avoidance learning, which might manifest as antici-

patory anxiety (Gray, 1982, cited in Cloninger, 2002, p. 1379). The thalamo-cingulate connects part of the hypothalamus, thalamus, cingulate gyrus, and hippocampus in a two-way circuit that is important in social interactions and attachment (MacLean, 1990, cited in Cloninger, 2002, p. 1381). The ventral striato-thalamic-prefrontal circuit is involved in persistence and reward-guided choice behavior (Schultz et al., 1998; Gusnard et al., 2001, cited in Cloninger, 2002, p. 1381).

NEUROIMAGING OF PERSONALITY DISORDERS

A review of the imaging literature on personality disorders shows that the greatest volume is on BPD, with less volume on antisocial personality disorder (ASPD) and schizotypal personality disorder (SPD). Data on the other personality disorders are presumed on studies of traits common in those disorders (for example, data on social phobia as a model for avoidant personality disorder). Neurobiological studies of Cluster B disorders have focused on BPD and ASPD, and most of the studies focus on specific functions such as emotional processing (mood disorders), impulsivity, and social relatedness (Nahas et al., 2005).

Lis et al. (2007) collected the literature available on BPD. In their review, they find there is disagreement and sometimes contradiction between neuroimaging studies, even when the same technology and procedures are used. In general, PET studies have demonstrated that patients with BPD have low metabolism in the dorso-lateral frontal cortex (as noted above, responsible for executive functions), anterior cingulate cortex (related to recognition of affect), basal ganglia, and thalamus at resting state (De la Fuente et al., 1997; Goyer et al., 1994, cited in Lis et al., 2007). This includes the areas discussed above for both frontal executive functions and limbic emotional circuits. BPD patients without comorbid Axis I or II disorders show reduced frontal lobe volume (6.2%) without other significant differences (Lyo et al., 1998, cited in Lis et al., 2007). Several groups (Driessen et al., 2000; Tebartz van Elst et al., 2003, cited in Lis et al., 2007) have specifically imaged the limbic structures and found reduced volumes in hippocampus (memory and learning), amygdala (satiety and aggression), left orbitofrontal cortex (implicated in decision making), and right anterior cingulate cortex (ACC, emotional responding). Specifically, a small study ($N = 8$ patients with BPD) found significant reductions in hippocampal and amygdala volumes, 24% reduction of left orbitofrontal volume, and 26% reduction of right ACC

volume (Tebartz van Elst et al., 2003, cited in Nahas et al., 2005, pp. 631–632). When patients with BPD are studied with EEG to measure P3 event-related brain potential during auditory stimulus target, the BPD subjects have enhanced amplitude, failure of habituation, and lack of temporal synchronicity with P3b, suggesting a general failure of coordination among diverse cortical networks. Their P3 profile is similar to people of a younger age, suggesting failure of maturation (Meares et al., 2005, cited in Lis et al., 2007).

With functional neuroimaging, researchers can study areas of the brain that activate during a task. In one such study (Donegan et al., 2003, cited in Lis et al., 2007), fMRI was used to observe brain activation during presentation of emotional facial expressions. All people, including normal controls, showed greater activation in the left amygdala in response to faces than to neutral stimulus. People with BPD had greater activation in the amygdala and in the dorsal border of the amygdala, the bed nucleus of the stria terminalis, the lateral hypothalamic nuclei, the nucleus basalis (proposed as integrator of limbic information), and the frontal lobes. BPD participants also reported difficulty with neutral faces, interpreting them as negative or threatening. When borderline patients are presented with scripts of abandonment, PET studies have shown increased activation of the bilateral dorsolateral prefrontal cortex and right cuneus and decreased activation in the medial prefrontal cortex (as above, important in conditioned responding, experiential emotion, and object recognition; Schmahl et al., cited in Lis et al., 2007). A small study of people with BPD exposed to trauma with and without post-traumatic stress disorder showed less activation of the orbitofrontal cortex, and there was no activation of Broca's area in patients with PTSD compared to those without, during recall of aversive but nontraumatic memories (Driessen et al., 2004, cited in Lis et al., 2007).

Magnetic resonance spectroscopy is used to examine metabolites in the brain as a measure of metabolism. Patients with BPD show reductions in N-acetylaspartate concentrations in the dorsolateral prefrontal cortex, suggesting a lower density of neurons and disturbed neuronal metabolism (van Elst et al., 2001, cited in Lis et al., 2007). Subjects with BPD have decreased metabolic responses in executive areas (specifically the orbital and medial prefrontal cortex and anterior cingulate, frontal, and temporal cortex) to pharmacological challenges with serotonergic agonists like fenfluramine or meta-chlorophenylpiperazine (Siever et al., 1999; Solloff et al., 2002; New et al., 2002, cited in Solloff, Price, Meltzer, Fabio, Frank, & Kaye, 2007). On single-photon emission computed tomography (SPECT), patients with

BPD and antisocial personality disorder show reduced regional cerebral blood flow in the right lateral temporal cortex and the polar and ventrolateral right prefrontal cortex (Goethals et al., 2005, cited in Lis et al., 2007).

McCloskey et al. (2005) concluded from reviewing the data on frontal lobes that the results may be contradictory (i.e., resting hypoactivity or hyperactivity) depending on trait variables like impulsivity or aggression. They determined that overall data support some sort of frontal and limbic dysregulation for patients who have BPD, but the exact changes and abnormalities have not been defined.

Patients with ASPD may process affect differently, as criminal psychopaths show less affect-related activity in inferior frontal gyrus, ACC, right amygdala, and ventral medial prefrontal cortex during negative affective encoding and rehearsal than during neutral phrases compared to nonpsychopathic criminals and controls. During the same tasks there were increases in activation of the left anterior superior temporal gyrus and right inferior frontal gyrus (Kiehl et al., 2001, cited in Nahas et al., 2005, p. 634). Psychopathic people have been found to have larger callosal white matter volume, which is responsible for increased functional interhemispheric functioning. The larger volumes are associated with blunted affect, lack of remorse, no close friends, lack of social closeness, low autonomic response (heart rate and skin conductance) to stress, and low spatial ability (Raine et al., 2003). Raine, Lencz, Bihrlé, LaCasse, and Colletti (2000) found that people with ASPD have decreased skin-conductance and heart-rate responses during tasks requiring them to read to an examiner a self-prepared recitation of flaws and failures, compared to controls without ASPD and/or substance dependence. In the same study, they found that the ASPD group had 11% volume reduction in prefrontal gray matter volume, and thus they concluded that deficits in this area of the brain may be linked to low arousal, poor fear conditioning, lack of conscience, and decision-making deficits. The ventromedial prefrontal cortex has been implicated as underlying social morality, for example, feelings of guilt and compassion, and it is activated on imaging studies of individuals viewing morally evocative photographs and during decisions to donate money to charity (Moll et al., 2007, 2006, cited in Miller, 2008). People with damage to that area make abnormal decisions about hypothetical moral dilemmas (Koenigs et al., 2007, cited in Miller, 2008). Psychopathic criminals were imaged on fMRI while responding to affectively laden words, and they showed less limbic activation than nonpsychopathic criminals and normal controls (Kiehl et al., 2001, cited in Pridmore,

Chambers, & McArthur, 2005). Schneider et al. (2000, cited in Pridmore et al., 2005) compared fMRI of people with ASPD to normal controls during classical conditioning with aversive stimulus and found that controls showed decreases in bilateral activity of the amygdala and dorsolateral prefrontal cortex during the acquisition phase, but the ASPD group showed increased activity. Soderstrom et al. (2002, cited in Pridmore et al., 2005) studied violent incarcerated offenders on resting SPECT and found a negative correlation between disturbed interpersonal attitudes (especially deceitful interpersonal style) and frontal and temporal perfusion (especially the head of the caudate nuclei and hippocampi). In general, Pridmore et al. (2005) concluded in reviewing available literature that no definitive conclusions can be made, but the research suggest psychopaths have decreased volume of prefrontal gray matter, decreased posterior hippocampal volume, increased callosal white matter volume, and reduced metabolism in the frontal cortex.

GENETIC CONTRIBUTION TO PERSONALITY

It is clear that genes (nature) and environment (nurture) both play a role in the development of adaptive and maladaptive (i.e., personality disordered) behaviors. There are linkages among families of certain disorders, with a varying contribution from genes and environment. Many behavioral genetic studies have come about either from postmortem studies that measure the neurotransmitter levels, animal models that knock out target areas of interest, and molecular genetic findings correlated to behaviors or disorders. There is no one-to-one correlation of gene to syndrome or behavior as there are with many traditional medical disorders, such as sickle cell disease. Instead there is a complex process of genes influencing neuroanatomical development, receptor density, and modulating factors that feed back on other systems among other targets.

Rutter (2007) discusses the various ways to look at the interactions of genes and environment. He categorizes them in the following way: epigenesis, variations in heritability influenced by environment, gene-environment correlations, and gene-environment interactions. The category of epigenesis is based on the idea that environments affect genes. He sites as an example the vast literature on the effects of the early nurturant experiences of rat pups on their maternal instincts when they become mothers. Regarding the second category, variations in heritability due to environment, he states there is contradictory and incon-

clusive evidence for such things as a stress-diathesis model. The gene-environment correlations include passive effects, such as parental genes shaping the rearing environment (these are assessed by twin studies); active effects, such as how the child's genes affect behaviors that select the environment; and evocative effects, such as how the child's genes affect behaviors that influence interpersonal interactions and other people's behaviors (the last two of which are studied through adoption studies). The final interaction, gene-environment, includes natural selection, individual adaptations to the environment during the formative period, variabilities in response to environmental hazards, and molecular genetic findings of susceptibility. He concludes that "the era of simply measuring heritability is over" (Rutter, 2007, p. 16). This often makes answering patient and family questions challenging, as they try to assuage their guilt about causing a problem or get a set answer on the odds that their children will develop a disease.

Several specific genes have been studied and implicated in traits associated with personality disorders, as discussed by the theories of personality development. The genetic studies of specific personality disorders are relatively rare (A. Heim & Westen, 2005). Twin and adoption studies provide the most definitive answers, as familial studies also include the influence of the environment. The data for BPD is mixed, with only modest evidence of heritability. The strongest genetic linkage is for schizotypal personality disorder, for which one study documents a 33% concordance rate among identical twins with only 7% concordance among fraternal twins (Torgersen, 1984, cited in A. Heim & Westen, 2005, p. 25). The concordance rate for monozygotic or identical twins is commonly compared to the rate of dizygotic or fraternal twins in medical studies, as the monozygotic set shares identical genes and presumably environment (unless the study is of twins reared apart), while the dizygotic twins share only some genes and the environment. The further away from 100% that the concordance rate is for monozygotic twins, the less the disease or trait is just due to genes. There are fewer studies on genetic association with BPD than for imaging studies. Heritability of BPD is suggested to be moderate to high. With regards to comorbidities within families, first-degree relatives of patients with Cluster A disorders have schizophrenic pathology and show similarities in biomarkers like abnormalities in eye tracking (Siever & Davis, 1991, cited in Paris, 2005, p. 122), relatives of patients with Cluster B disorders have impulsive disorders (Zanarini, 1993, cited in Paris, 2005, p. 122), and relatives of patients with Cluster C have anxiety disorders (Paris, 1997, cited in Paris, 2005, p. 122).

Adoption studies support evidence that antisocial personality disorder is both environmentally and genetically linked. The vulnerability of having a biological parent with an arrest record for antisocial behavior increases 4 times the risk of problems with aggressive behavior for adult adoptees (Cadoret, 1995, cited in A. Heim & Westen, 2005, p. 25). The concordance or criminality is 2–3 times higher for monozygotic than dizygotic twins (Cadoret, 1986, cited in Gabbard, 2000b, p. 495). The environment also plays an important role. Approximately 60% of variance in adolescent antisocial behavior (as studied among twins, siblings, and step-families) is accounted for by negative and conflictual parental behavior directed specifically at the adolescent. It appears that heritable and genetic characteristics in the children evoked harsh and inconsistent parenting in these specific children (Reiss et al., 1995, cited in Gabbard, 2000b, p. 496). Also, although there are fewer women than men with ASPD, the women with this disorder have a stronger genetic loading, or more antisocial relatives, than have the men with ASPD (Cloninger, 1975, cited in Cloninger, 2005, p. 145).

Overall, when personality disorder symptoms are compared through the use of twin studies, symptoms show moderate heritability of 40%–60% (Jang et al., 1996, cited in Cloninger, 2005, p. 146). There was a lower correlation of Cluster A symptoms (near 40%) than Clusters B and C (near 60%). However, when the environment is also taken into account through the use of adoption studies, the heritability of personality drops to 20%–30%. This indicates that the heritability estimates from twin studies are inflated by gene-environment interactions (Cloninger, 1998, cited in Cloninger, 2005, p. 148).

NEUROTRANSMITTERS IN PERSONALITY

Many of the major symptom clusters of BPD, such as impulsivity and aggression, appear to be highly heritable (Lis et al., 2007). Several neurotransmitter systems have been studied as implications for behavior such as impulsivity and aggression, and for the mechanisms of genetic transmission of traits. These include the neurotransmitters that are the targets of many psychotropic medications, such as serotonin (5-HT), as well as transmitters that are thought to be important in neurodevelopment and reactions to stress.

Corticotropin-releasing factor (CRF) has been implicated in the long-lasting effects of early childhood trauma that present as depression in people with and without personality disorders as adults (C. Heim &

Nemeroff, 2001). CRF is released during stress and goes on to stimulate the release of proopiomelanocortin derivatives, adrenocorticotropin, and beta-endorphin. Adrenocorticotropin goes on to stimulate synthesis and secretion of glucocorticoids, which have wide-ranging metabolic and immunological effects. Microinjections of CRF can induce fear and anxiety behaviors and influence firing rates of noradrenergic and serotonergic neurons (C. Heim & Nemeroff, 2001).

A short allele of the 5-HT transporter gene serotonin transporter gene promoter polymorphism (5-HTTLPR) has been associated with violent behavior in people (Retz et al., 2004, cited in Lis et al., 2007). This may support the use of selective serotonin reuptake inhibitors (SSRIs) in patients with BPD (Lis et al., 2007). This gene has also been implicated in susceptibility to stressful events. People with one or two copies of the short allele in 5-HTTLPR exhibit greater amygdala neuronal activity in response to fearful stimuli than individuals with the longer allele (Casi et al., 2003). The number of stressful events in the participant's life did not differ depending on the genotype (i.e., the gene did not influence the stress from the environment), but individuals with the short allele who were exposed to stressful life events were much more likely than those with stress and the long allele to self-report depression. The short allele is also associated with anxiety-related traits, like neuroticism, and character traits (from Cloninger's Temperament and Character Inventory) of low self-directedness and low cooperativeness (Hamer et al., 1999; Thierry et al., 2004, cited in Cloninger, 2005, pp. 148–149). Soloff et al. (2007) found increased altanserin (a high-affinity 5HT_{2A} antagonist) binding in the hippocampus of people with BPD, especially ones who were not depressed, compared to normal controls. This suggests less serotonergic agonism in the identified areas, and that leads to upregulation of number or responsiveness of postsynaptic receptors to compensate. Their finding is similar to postmortem studies of suicide victims that suggest serotonergic signal, especially in the prefrontal cortex, and compensatory upregulation of postsynaptic 5HT_{2A} receptors in people with suicide completions and impulsivity (Mann & Stoff, 1997, cited in Soloff et al., 2007). Although the above study found statistically significant differences between people with BPD and normal controls in altanserin binding in the hippocampus, they found a trend (without statistical significance) in the area of the prefrontal cortex (which, along with the frontal cortex and occipital cortex, is the site of the most 5HT_{2A} binding). Another study of people with diverse diagnoses who attempted suicide found an inverse correlation of this frontal 5HT_{2A} binding and

hopelessness and harm avoidance (from the Temperament and Character Inventory) and direct correlation with self-directedness and cooperation (Audenaert et al., 2001, cited in Soloff et al., 2007).

The MAOA gene encodes MAOA enzyme, which is responsible for metabolizing norepinephrine, serotonin, and dopamine. Genetic polymorphism resulting in MAOA deficiency has been linked to criminal behavior in people who were abused as children, compared to other abused children without the deficiency who do not go on to commit criminal acts (Caspi et al., 2002, cited in Lis et al., 2007). Taylor and Kim-Cohen (2007) performed a meta-analysis of the data available on studies of the polymorphisms of the MAOA gene. They found that across eight different studies of childhood maltreatment in people with genes coding for low levels of MAOA enzyme activity there is a correlation with an outcome of antisocial behavior. Because the effect sizes are different in the different studies of various age and other variables, they concluded that the environmental factor of age of first abuse and developmental timing of maltreatment help explain the variability in phenotype as adults. There is a functional polymorphism in the COMT gene, the gene that codes for catechol-O-methyltransferase, which is involved in metabolism of dopamine released into synapses, that, when comorbid with adolescent-onset cannabis use, can predict adult psychotic symptoms. People who have a low-activity form of COMT have higher scores of harm avoidance, a trait on the Temperament and Character Inventory (Enoch et al., 2003, cited in Cloninger, 2005, p. 148). People with high-activity forms of COMT, and thus higher dopamine catabolism, including in the prefrontal cortex, have more perseveration errors on the Wisconsin Card Sorting Test (Egan et al., 2001, cited in Cloninger, 2000, p. 149). This task is frequently abnormal in people with schizophrenia. Subtypes of the dopamine D4 receptor (DRD4) have higher avoidant and obsessive symptoms, and that is not predicted by theories that link dopamine with novelty seeking (and no significant associations were found with Cloninger's temperament measures; Joyce, Rogers, Miller, Mulder, Luty, & Kennedy, 2003). A subtype of the dopamine D3 receptor (DRD3) is associated with higher rates of obsessive symptoms and obsessive-compulsive personality disorder. These genetic defects have not been directly linked to personality disorders but are implicated in many of the symptoms and comorbidities experienced by persons with personality disorders.

These genes also interact with each other. For example, novelty-seeking scores are higher in the presence than in the absence of DRD4 when there is no short

version of 5-HTTLPR and there is high-activity COMT genotype (Benjamin et al., 2000, cited in Cloninger, 2005, p. 149). Also, unrelated individuals compared to each other and siblings compared to each other have similar scores on novelty seeking only when they share all three polymorphisms (Benjamin et al., 2000; Strobel et al., 2003, cited in Cloninger, 2005, p. 149). Likewise, the temperament dimension of persistence involves a three-way interaction of DRD4, DRD3, and serotonin receptor gene type 2c (5-HT2c) (Ebstein et al., 1997, cited in Cloninger, 2005, p. 149).

THEORETICAL PSYCHODYNAMIC MODELS FOR PERSONALITY DISORDERS

To begin our discussion of how people come to suffer from personality disorders, we'll start with some of the theoretical psychological models. These models flow from an understanding of the disordered state as something problematic in the person's development. The problems can be an innate state of the person, for example, his or her temperament. The problem may lie in the parental role models or in the interaction between the parent and the child. Table 19.2 shows a simplified depiction of the psychological stages of childhood development. This includes stages of development as they are understood by Erikson, Freud, and Piaget compared at roughly equivalent ages. It also includes problems that may be associated with struggles or trauma at that level, as well as defenses used at that stage. This should not be viewed as a one-to-one correlation of where people with these disorders are stuck, but as a way to understand what tasks they struggle with. Since these theories are based in developmental tasks and struggles of childhood and adolescents, there are common themes in many of the different disorders of invalidation (not being heard) and powerlessness. You can see when therapists talk about patients as being very "primitive," those patients are on the top of the table. They are still struggling with, or regressed to, the most primitive developmental tasks. As opposed to the psychoanalytic conflict model, these most primitive patients can be best understood from a "deficit model" of illness. This model understands that some developmental deficit left this person with weakened psychic structures so that he or she cannot feel whole or secure. As a result, these individuals require constant input and feedback from the environment to contain themselves and stay in psychological homeostasis (Gabbard, 2000b, p. 4).

19.2

Psychological Development Stages

	ERIKSON'S EPIGENETIC PRINCIPLES	FREUD'S PSYCHOSEXUAL STAGES	PIAGET	ASSOCIATED PROBLEMS	DEFENSES
0–1 year	Basic trust vs. mistrust	Oral pre-oedipal dyadic	Sensorimotor	Abandonment, symbiosis, differentiation, borderline, paranoid-schizoid, narcissism	Projection, incorporation, denial, displacement, turning against self
1–3 years	Autonomy vs. shame and doubt	Anal		Rapprochement, object constancy, cleanliness, control, OCD, dependency	Identification, undoing, reaction formation, isolation, regression
3–5 years	Initiative vs. guilt	Phallic-oedipal triadic	Preoperational: animism	Fear of castration, neurosis	Intellectualization
6–11 years	Industry vs. inferiority	Latency	Concrete operations	Guilt, disapproval	Regression, symbolization, sublimation
11 yrs to end of adolescence	Identity vs. role diffusion		Formal operations	Delinquent behavior	

These theories also do not always fit with the *DSM-IV*, as this revision of diagnostic criteria is based on overt behaviors rather than dynamic understanding (Gabbard, 2000b, p. 518). The theories can be very useful in informing the conceptualization of the patient and in directing the psychotherapy. Various psychodynamic theories view normal and pathological development very differently. For example, the psychoanalytic model regards development as a single-track rail along which stops occur so that adult pathology reflects fixations at, or regressions to, phases that would have been normal at some point in development. This is in contradiction to Bowlby's alternative attachment theory, which regards development as a single main route that branches out into a range of distinct tracts (Fonagy, 2001, p. 2). Some theories emphasize the real world of the child and the effect of the environment on his or her development, and some emphasize the internal world and how the child perceives the environment. Fonagy (2001), from an attachment theory, posits that early relationships are not critical in influencing the quality of later

relationships but instead develop in the person a mental processing system that later generates mental representations, including relationship representations.

Much research has been done on infants' attachment style and later psychopathology, and it is the disorganized/disoriented infant category that has the strongest predictive significance for later disturbance (Fonagy, 2001, p. 30). These are children who in Ainsworth's Strange Situation seek proximity to the caretaker in strange and disorienting ways, such as walking backwards or freezing (Fonagy, 2001, p. 20).

The psychodynamic theories, used to help us understand the development of the personality disorders, can then be used to direct psychotherapies. These theories and approaches are summarized in depth by Gabbard (2000b) and are summarized here. In Cluster A, patients tend to have an introjective pathology, which can be seen as an exaggerated quest for self-identity instead of relatedness to other people and dismissing or avoidant pathology in dealing with other people (Blatt & Blass, 1996, cited in Fonagy, 2001, p. 34). They deny

needing help from people to protect themselves from the possibility that the caretaker eventually may not be available (Dozier, 1990, cited in Fonagy, 2001, p. 34). People with paranoia can be seen as having very low self-esteem, which leads to a need to control others as compensation, so they act grandiose or special. Developmentally they lack object constancy (usually established by age 3 years), so they are unable to maintain a loving connection with an internalized version of their caretaker. They have problems with people in authority, as they fear humiliation or forced submission, and this can be a barrier to treatment if the therapist is only seen as an authority figure and cannot establish an alliance. They only seek treatment when the paranoid and grandiose defenses break down and they become depressed and anxious (Gabbard, 2000b, pp. 388–389). These patients do not do well in groups and need an empathic therapist who understands the patient's need to project and validates the patient's perception as worthwhile for discussion. As they are guarded, they may need time and silence to open up; they may respond better to this approach than to intrusive questioning. The goal of work with paranoid patients is to shift the origin of problems from an outside, external site to an internal one. They must also be able to tolerate and experience the vulnerable, weak, and defective feelings that come from transforming from a paranoid cognition to the depressive position for which their paranoia was protective (Gabbard, 2000b, pp. 389–392). As patients learn to feel trust for the therapist, they can mourn their defective attachments to primary caregivers, reveal their need for acceptance, and internalize this new type of relationship model (Meissner, 1976, 1995, cited in Gabbard, 2000b, pp. 392–393). The therapist helps the patient convert his or her thinking by encouraging "creative doubt" about misperceptions of the world, so that paranoid distorted thinking becomes less certain (Meissner, 1986, cited in Gabbard, 2000b, p. 392).

Schizoid individuals are a contradiction of strivings to be connected but instead isolating. Once they open up in therapy, it becomes apparent that this is due to a conviction that since they didn't receive what they needed from the mother, they no longer attempt to connect (Nachmani 1984, cited in Gabbard, 2000b, p. 400). The schizoid retreat can be seen as a defense against a conflict between a wish to relate to others and the fear that one's neediness will harm others (Fairbairn, 1954, cited in Gabbard, 2000b, p. 400). They fear taking anything from someone, as it can risk triggering longings for dependency, and love is equated with losing one's own identity and destroying the other person in this fusion (Gabbard, 2000b, p. 401). They have more

powerful and grandiose fantasies in inverse proportion to their self-esteem (Nachmani, 1984, cited in Gabbard, 2000b, p. 401). As object relations theorists view the "basic fault" of these patients as significantly inadequate mothering (Balint, 1979, cited in Gabbard, 2000b, p. 400), the therapy is directed at providing a new and trustworthy relationship for internalization (Gabbard, 2000b, p. 402).

Much has been written about the contributing factors to BPD (in Cluster B) psychopathology. There are three overarching factors proposed in this etiology: traumatic and chaotic home life with neglect, abuse, separation, and invalidation of feelings and needs; biologically based vulnerability of temperament with difficulty being soothed; and triggering events like relationships or trauma that act as a catalyst for symptoms (Zanarini & Frankenburg, 1997, cited in Gabbard, 2000b, pp. 426–427). Abuse is a very important factor, as 60% of BPD patients have suffered sexual abuse (Gabbard, 2000b, p. 424). Kernberg viewed these patients as being fixed at the rapprochement subphase (approximately 16–24 months) of separation-individuation (Gabbard, 2000b, pp. 419–420). Due to the lack of object constancy, they cannot self-soothe while the mother is absent and thus cannot tolerate aloneness and feel empty. They also split people (themselves or caretakers) into all good or bad, as they cannot integrate a more balanced view (Gabbard, 2000b, p. 419–420). They stop thinking about feelings and reflections of the self and others, as they cannot comprehend their abusers. This leads to a lack of sense of agency and cohesive sense of self, so that they disavow ownership of their own bodies and actions (Fonagy & Target, 1995, cited in Gabbard, 2000b, p. 426). This understanding can help the therapist form a stronger alliance by validating and acknowledging the effects of early trauma and the patient's struggle forming a trusting relationship (Gabbard, 2000, p. 437). The therapist can then help the patient identify emotional states, connect feelings and actions, and become reflective about self-destructive behaviors (Gabbard, 2000b, p. 441).

Also in the Cluster B disorders is narcissistic personality disorder. These patients suffer from a developmental arrest at the separation phase, rather than the individuation phase, as in BPD (Rinsley et al., 1980, cited in Gabbard, 2000b, p. 474). This results in a "pseudo-mature" child who was allowed to separate psychologically from the caretaker only on the condition that the subsequent achievements reflect a relation to him or her. There appear to be two general subtypes in this set (based on the psychodynamic understanding, as opposite ends of a continuum, not as delineated in

the *DSM-IV*): the oblivious type, approximated by the writings of Kernberg, and the hypervigilant type, approximated by the writings of Kohut (Gabbard, 2000b, p. 473). Oblivious types seem to have no awareness of their impact on others, need to be the center of the universe, and appear as if they cannot have their feelings hurt by others. The hypervigilant type is very sensitive to how others react to him or her, completely directs focus on other people, and frequently feels ashamed (Gabbard, 2000b, p. 467). Kohut (1971, 1977, 1984, cited in Gabbard, 2000b, p. 469) proposed that developmentally the narcissist is arrested at a stage where the child needs specific responses from people in the environment to be a cohesive person. Parental empathic failure caused this fixation, since the parents did not admire and validate age-appropriate exhibitionism, did not offer twinship (being like the parent), and did not provide models worthy of idealization. The goal for treatment with these folks is to move them from needing less mature to more appropriate self-objects as sources of gratification for the self. The therapist empathizes with the patient's transference (mirroring, idealizing, and twinship) as the way of reactivating failed parental relationships, and then the therapist interprets rather than gratifies the yearning to be soothed (Kohut 1984, cited in Gabbard, 2000b, pp. 475–476). Kernberg (1970, cited in Gabbard, 2000b, pp. 470–473) saw the narcissist's pathologically grandiose self as a defense against investment in and dependency on others. Narcissists idealize their own self-image and project the unacceptable features of their own self-image onto others. Their grandiosity can be like a "pseudo-self-sufficiency" where they deny the need for caretaking and nurturance but are frequently trying to impress others and gain approval. They suffer from envy as they constantly compare themselves to others and end up tormented by inferiority and yearning to possess what others have. To deal with the envy, they devalue others so that there is a void of internal object representations, leaving them feeling lonely and empty. They try to fill the emptiness with constant admiration from others. The therapist should interpret idealization as a defense against split-off feelings of contempt. The therapist also needs to focus on how the patient's envy prevents him or her from receiving or acknowledging help, and defensive maneuvers that devalue and control the therapist to keep him or her at a distance must be confronted (Gabbard, 2000b, pp. 477–478). Kernberg (1984, cited in Gabbard, 2000b, p. 479) suggested that a subset of narcissists with the most ego weakness should have supportive therapy. This group functions at an overtly borderline level and demonstrate excessive cruelty and sadism, prominent

antisocial features, lack of involvement with other people, have paranoid reactions to people and are prone to rage, which is rationalized as someone else's fault.

Also in Cluster B, ASPD reflects significant genetic heritability and environmental influences. Developmentally, many of the same factors that lead to BPD in women lead to ASPD in men (and perhaps there is a mislabeling of patients as one or the other based on their gender (Gabbard, 2000b, p. 495). If I were to write a recipe to create a criminal, it would include a family history of a violent alcoholic father who is incarcerated; low intelligence, concrete cognitions, or history of traumatic brain injury and resulting disinhibitions and impulsivity; a history of substance abuse; brutalization by extreme poverty; victimization by abuse and a history of witnessing violence; and harsh, inconsistent parenting. Antisocial personalities can be difficult to work with because of their seeming "lacking in basic humanness" due to the absence of any moral sense and because they externalize all their problems (Gabbard, 2000b, pp. 497–499). Regardless of the contribution of biology or environment, the processes that commonly take place in the development of antisocial people include detachment from all relationships and affective experiences, sadistic attempts to bond with others so as to exercise power and destruction, and significant problems with the internalization of others (Meloy, 1988, cited in Gabbard, 2000b, p. 497). The least psychopathic of these individuals have neurotic character traits but behave in an antisocial manner due to unconscious guilt, as they hope to be caught and punished (Gabbard, 2000b, p. 500). The predictors of positive treatment outcomes include the presence of anxiety (as it shows concern for his or her behavior), diagnosis of depression (as it represents some capacity for remorse), and diagnosis of psychotic disorder (as it suggests pharmacological interventions may improve the condition; Gabbard & Coyne, 1987, cited in Gabbard, 2000b, p. 503). Most of these patients require treatment in an institutional or residential setting, because this prevents them from discharging their impulses in acting-out behaviors and forces them to get in touch with their affective state (Gabbard, 2000b, p. 500). This also allows for an important group confrontation of the "con artist" techniques, and for consistent consequences for rule breaking and opportunities to neutralize bargaining (Gabbard, 2000b, p. 502). As is frequently taught to children with impulsive acting-out behavior, it is useful to teach them a triangle of thinking, feeling, and doing. This involves teaching that impulses and actions grow out of feelings. As many of them have no vocabulary for emotions and cannot describe their internal states, they must be

taught this language, such as is done with children with a feelings diagram. Then they must be taught to put brakes on the impulses and insert a thought between impulses and actions. This can be aided by the use of medications, if necessary, but also relaxation and counting techniques, and later review of the consequences of the actions. When the patient does break the rules, it must be confronted in the “here and now” of the milieu (Gabbard, 2000b, p. 506). In individual therapy, the therapist must confront denial and minimization of antisocial behavior. The patient may frequently, out of unconscious envy of the therapist’s positive qualities, delight in tricking the therapist so as to avoid a threat to his or her grandiose self. The patient can take delight in avoiding being changed by the therapist if the therapist has great expectations for improvement (Gabbard, 2000b, pp. 510–512). As with dealing with oppositional youth, it is important to avoid a power struggle that further continues the patient’s own dysfunctional way of relating to people. It is also important to be honest about natural and logical consequences of their behavior, rather than being threatening and harsh as an angry reaction to the patient.

Glen was a 16-year-old with conduct disorder who was admitted to a psychotherapeutic institution in the custody of juvenile justice authorities due to running away, drug possession, and aggression toward family members. In this setting, he frequently bullied and threatened peers and staff. He would tell some staff stories of an abusive childhood with an alcoholic father who was currently incarcerated to evoke sympathy, and these staff would defend him and punish his peers for teasing him. He would avoid getting close to peers by making inflammatory racist statements that his mother stated were not his true beliefs (as he had friends of those races at home). He would attempt to have staff give him privileges he had not earned, and he would bargain for things by promising minor things (like bathing, which was an expectation on the unit) for rewards. For a period he had rages in which he would run out of the room screaming, cursing, and slamming doors every time his psychiatrist would point out that she was aware of his behavior and what the resulting unit consequence for this was. Eventually when she pointed out his powerlessness in the situation, and his futility improving it with the current maladaptive behaviors, he was able to show interest in learning how to control his impulses. She acknowledged how difficult it was to admit that powerlessness, as his omnipotent fantasy protected him from memories of significant abuse. The turning point came when she acknowledged to him that neither she nor he would win or lose, and the situation

was a “checkmate.” If he did not participate in testing required for him to be on the unit, he would have to return to a restrictive jail environment to make room for someone who could participate in the program. She would feel no pain at her inability to help him, as she acknowledged her powerlessness to help some people. If he did participate, she would not see it as winning a battle with him, as she acknowledged it would be done by his own free will.

The final discussion of Cluster B pathology is on the histrionic personality disorder. Developmentally these patients are fixated at primitive dyadic object relations level (see the primitive, pre-oedipal stage in Table 19.2), which predicts their characteristic clinging, masochism, paranoia, primitive defenses (like splitting and idealization), and lack of ability to not be overwhelmed by separation from love objects (Gabbard, 2000b, p. 521). This fixation is likely due to maternal deprivation at the oral stage, resulting in difficulty later resolving the oedipal situation (Blacker & Tupin, 1977, cited in Gabbard, 2000b, p. 525). Because of oedipal longings for their fathers, women with this disorder may choose inappropriate partners as a defense or tinge all sexuality with incestuous meanings or feel anger toward their fathers without knowing why (Gabbard, 2000b, p. 526). They lack detail in their cognitive functioning, and they resent being forced to concentrate. This parallels their inhibition of information processing to blunt strong emotions, so they use repression, denial, dissociation, and suppression as defenses. This is in contradiction to their exaggerated, but still shallow, emotional displays, which are an attempt at manipulating and eliciting responses from others as they focus on whether or not people are paying them attention (Gabbard, 2000b, p. 524). Since they are superficial and shallow, they are defended from feeling genuine affective states. The exaggerated behavior may grow from not being recognized during childhood by parents who were self-absorbed, resentful, or unavailable (Gabbard, 2000b, pp. 525–526). From attachment styles, they can appear to be avoidantly attached so that they down-regulate affect and have greater incidence of somatic symptoms (Fonagy, 2001, pp. 14, 33). In treatment, the therapist must convey that the patient is being heard and that more details are needed for him or her to understand the situation. The patient can grow a sense of self by internalizing the observations the therapist makes of the patient’s behavior out loud (Gabbard, 2000b, p. 529). Patients should be taught a sense of agency so that they no longer see themselves only as passive victims (Horowitz, 1977, cited in Gabbard, 2000b, p. 530). They may try to learn about the therapist’s life so they can become like the therapist, rather

than developing their own identity, and to please the therapist (Gabbard, 2000b, p. 530).

The Cluster C disorders are characterized by fear. The early psychoanalysts saw obsessive-compulsive symptoms as a regression from the oedipal stage to the anal stage in order to prevent the experience of castration anxiety. The punitive superego drives defenses like isolation of affect, intellectualization, reaction formation, undoing, and displacement (Gabbard, 2000b, p. 549). More recent thinking suggests that high levels of self-doubt contribute to this pathology. Obsessive-compulsives did not feel valued or loved as children, which could be due to parental coldness or higher levels of need in the child. They thus have “strong unfulfilled dependent yearnings and a reservoir of rage directed at the parents for not being more emotionally available” (Gabbard, 2000b, pp. 549–550). Intimate relationships create the risk that the individual will wish to be taken care of and thus a risk of being “out of control” and result in resentment. They fear that their own destructive wishes and high levels of aggression will drive others away. They desperately try to feel approved but drive underlings away by being controlling and superiors away by being obsequious (Gabbard, 2000b, p. 550). They seek perfection to reach parental approval but are not satisfied with their own achievements. They seek to be logical and rational and dampen all affect. Most obsessive-compulsive patients resent the idea of psychodynamic therapy because the unconscious threatens the sense of control. In therapy they may ramble as a response to a threat of intense affect; this can be interpreted to the patient as a way of keeping at an emotional distance. They may have a fantasy of earning love and esteem if they become the perfect patient. The therapist should honestly and openly address the patient’s feelings, even if they are denied by the patient. The therapist facilitates changes by being neutral though the patient’s transference viewing of the therapist as critical, so that the patient can begin to see that his or her own critical attitude and prohibitions of sexuality, dependency, and aggression are his or her own (Gabbard, 2000b, pp. 555–559).

Also in Cluster C is avoidant personality disorder (AVPD). People with AVPD fear situations in which they might be vulnerable. They suffer shame, as they feel they do not measure up to an internal standard. There are many developmental points that can cause shame, such as bladder and bowel accidents or being rebuked by parents (Gabbard, 2000b, p. 562). They fail to have adequate self-object responses, and they see their own developmental needs as excessive (Miliora 1998, cited in Gabbard, 2000b, p. 563). Therapy involves facing a

feared situation with an empathic appreciation of the shame of this exposure (Gabbard, 2000b, p. 563).

Dependent personality disorder is also in Cluster C, and involves patients who react to fear of abandonment by becoming submissive and clinging (Hirshfeld et al., 1991, cited in Gabbard, 2000b, p. 567). Patients with dependent personality disorder come from families low in expressiveness, low in independence, and high in control (Head et al., 1991; Baker et al., 1996, cited in Gabbard, 2000b, p. 567). These patients as children did not have a struggle with one particular developmental stage but rather had enmeshed and insecure attachments with parents who communicated that the world is a scary place and thwarted independence. The therapy is full of the patient attempting to get the therapist to tell or her what to do, and the therapist frustrating these wishes and encouraging the patient to think about what is so frightening about independence (Gabbard, 2000b, pp. 567–569). Time-limited therapy is useful because from the beginning the patient has to confront anxieties about loss and independence when the sessions are over (Gunderson, 1988, cited in Gabbard, 2000b, p. 570).

THEORETICAL NEUROBIOLOGICAL MODELS OF PERSONALITY DISORDERS

Models for personality disorders can also be based on biological theories, rather than psychodynamically focused on how the person develops. These models involve neuroanatomy and functional areas of the brain responsible for behavior, the neurotransmitters that function and modulate those systems, and the environmental effects on the person that influence development and interpersonal relationships. For example, attachment takes into account the person’s genetically prewired capacity to attach, the individuals in the environment, and the events that occur during development, such as trauma. The predominant models of personality converge on four broad domains of functioning: extraversion versus introversion, antagonism versus agreeableness, constraint versus impulsivity, and emotional dysregulation versus emotional stability (Widiger & Mullins-Sweatt, 2005, p. 44).

Table 19.3 shows how these models collide on the same four domains. Paris (2005) reviewed three of the neurobiological dimensional models of personality that can be loosely superimposed on these domains and included an overview of the supporting data. He concluded that as none have strong empirical support, the current dimensions of personality should be derived

from factor analysis rather than from neurobiological theories for now. The five-factor model of personality is a trait model that explains how traits covary and can be identified by factor analysis. Personality disorders can be understood as extremes of normal traits (A. Heim & Westen, 2005, p. 22). Table 19.4 lists the components of this and the following theories, including the impact of biology on the following theories.

The most developed and studied trait model correlated to neurobiology is Cloninger's model (A. Heim & Westen, 2005, p. 23). The premise is that temperament consists of automatic responses based on procedural learning and is linked to particular neurotransmitters. There are four temperamental dimensions (novelty seeking, harm avoidance, reward dependence, and persistence). There are also three character dimensions, which are self-aware and based on insight learning, influence voluntary actions, and determine the presence of a personality disorder (Cloninger, 1993, cited in A. Heim & Westen, 2005, pp. 23–24). These are self-directedness, cooperativeness, and self-transcendence. Novelty seeking is thought to be linked to dopamine, and to mediate the brain's incentive or behavioral activation system through midbrain (ventral tegmental areas) dopaminergic neurons projecting to the forebrain. Harm avoidance is linked to serotonin and mediates the brain's punishment or behavioral inhibition system through the dorsal raphe nuclei in the midbrain projecting to the septum, hippocampus, and prefrontal cortex. Reward dependence is linked to norepinephrine and mediates learning through paired associations. The location for this action is the locus coeruleus in the pons with projections to the hypothalamus, amygdala, hippocampus, and neocortex (Cloninger, 1993, cited in Paris, 2005). Persistence was added to the model later, and compulsive traits are thought to be linked to prefrontal activity, especially the anterior cingulate (Cloninger, 2004, cited in Paris, 2005). Personality disorders exist when patients are low on character dimensions of self-directedness and cooperativeness (Cloninger, 1998, cited in A. Heim & Westen, 2005, p. 24). The temperament dimensions distinguish which cluster patients fall into. Cluster A disorders are low in reward dependence; Cluster B disorders are associated with high novelty seeking; and Cluster C disorders are associated with high harm avoidance. Paris (2005) explores the large amount of data that support and contradict this theory. For example, a relationship between the D4 dopamine receptor gene and novelty seeking has been reported by as many papers as have not found the association. One group found the link only in females, and another found that gene is interactive with the serotonin receptor. This

suggests that the model may be too reductionistic to be supported by the data.

The same is true for the other two models Paris (2005) reviews. Depue and Lenzenweger's neurodimensional model envisions personality disorders as phenotypes resulting from the interaction of neurobehavioral systems underlying basic traits (Depue & Lenzenweger, 2001, cited in A. Heim & Westen, 2005, p. 24). This model of personality is built on four higher-order trait dimensions linked to neurotransmitters: agentic extraversion, affiliation, neuroticism and harm avoidance, and non-affective constraint (2001, cited in Paris, 2005). These traits are thought to be related in this order to dopaminergic brain systems and related to positive incentive motivation (Depue & Collins 1999, cited in Paris 2005), neuropeptides such as oxytocin and vasopressin to promote longer-term affective bonds (Insel, 1997, cited in Paris 2005), norepinephrine related to the amygdala and fear responses, and lastly serotonergic brain systems with wide innervation. Paris (2005) reports that there has not been much research to support this theory.

Siever and Davis's model was designed to describe the neurobiological dimensions underlying all categories of psychopathology, including Axis I and personality disorders. The dimensions are cognitive/perceptual, impulsivity/aggression, affect regulation, and anxiety/inhibition. They are thought to fall on a continuum, with lesser forms responsible for personality disorders, and the more severe ones responsible for Axis I pathology (Siever & Davis, 1991, cited in A. Heim & Westen, 2005, p. 23). Their cognitive/perceptual dimension is responsible for thought disorders and attention and is mediated through dopamine. The impulsivity/aggression dimension is responsible for impulse control disorders and can be conceptualized as capacity to inhibit behavior mediated through serotonin. The affect regulation dimension is responsible for mood disorders and is mediated through noradrenergic-cholinergic balance. The anxiety/inhibition dimension is responsible for anxiety disorders for assessing danger and is associated with arousal and is proposed to be due to low dopamine and high serotonin levels. There is not consistent evidence that neurotransmitter variation corresponds to trait dimensions, or that the personality disorders are on a continuum with other disorders (Paris, 2005).

The strongest evidence for the continuum hypothesis comes from the conceptualization of schizotypal personality disorder (SPD) as a milder form of schizophrenia. In fact, criteria met for schizotypal personality disorder predict a diagnosis of schizophrenia at long-term follow-up (Fenton & McGlashan, 1989, cited

19.3

Synthesis of Personality Traits Into Four Broad Domains

LIVESLY'S DIMENSIONAL ASSESSMENT OF PERSONALITY PATHOLOGY	CLONINGER	SIEVER & DAVIS	DEPUE et al.	LARA & AKISKAL
Extraversion vs. introversion	Reward dependence (sociable vs. aloof)	Anxiety	Agenic extraversion	High vs. low fear
Antagonism vs. agreeableness	Persistence and cooperativeness (over- vs. underachiever)	Cognitive	Affiliation	High vs. low anger
Constraint vs. impulsivity	Novelty seeking (impulsive vs. rigid)	Impulsivity	Neuroticism and fear	High fear vs. high anger
Emotional dysregulation vs. stability	Harm avoidance (and self-directedness) (anxious vs. risk taking)	Affective	Nonaffective constraint	Low fear/high anger vs. high fear/ low anger

in Gabbard, 2000b, p. 397). On volume measures on imaging studies, there is decreased volume of the temporal lobes and ventricular enlargement in both SPD and schizophrenia. However, in SPD there is preserved volume of the frontal lobes (implicated in active psychotic symptoms and executive functioning in the dopamine hypothesis) compared to schizophrenia (Siever, 1995, cited in Coccaro & Siever, 2005, p. 158). Within a group of patients with SPD, there is an inverse correlation between size of the frontal lobe and executive functions (Raine et al., 1992, cited in Nahas et al., 2005, p. 629). Additionally, on functional imaging, the dorso-lateral prefrontal cortex fails to activate in patients with SPD in response to an executive function test, but the deficit is more pronounced in patients with schizophrenia (Buchsbaum et al., 2002, cited in Coccaro & Siever, 2005, pp. 158–159). With the administration of 2-deoxyglucose, which activates stress-sensitive cortical systems, patients with schizophrenia show greater cortisol response than normal controls, but patients with SPD show normal or reduced cortisol activation (Siever & Davis, 2004, cited in Coccaro & Siever, 2005, p. 157). The medial prefrontal cortex is hypothesized to be protective for patients with SPD against development of schizophrenia, because the metabolic rates in this area, Brodmann 10, are distinctly higher than the metabolic rates in normal controls or persons with schizophrenia

(Buchsbaum et al., 2002, cited in Nahas et al., 2005, pp. 629–630). It has also been proposed that AVPD on the Cluster C spectrum may be a continuum of social phobia on Axis I (Dahl, 1996, et al., cited in Gabbard, 2000b, p. 561). Some of the medicines used to treat social phobia, like paroxetine, have shown benefit for AVPD (Stein et al., 1998, cited in Gabbard, 2000b, p. 561).

Lara and Akiskal (2006) propose their own theory of personality disorders based on a bidimensional model of fear and anger traits. In their model, excessive fear is the basis for anxiety disorders, depression, and Cluster C personality disorders. The amygdala has the central role in fear detection. Fear is proportional to serotonergic tone and cortisol levels, and inversely proportional to noradrenergic tone, GABAergic modulation, and adenosine activity. Low fear is responsible for reckless impulsivity and the hyperactivity of manic, ADHD, and disruptive behavior disorder patients. Excessive anger is the common basis of bipolar disorders, Cluster B personality disorders, substance abuse, and other impulsive dependency drives. It is related conceptually to drive, motivation, and pleasure and localized in the model to nucleus accumbens or ventral striatum (the ventral portion of the basal ganglia). High anger may be related to enhanced dopamine states, but also modulated by glutamate through AMPA receptors and adenosine.

Theories of Personality Models

	CLONINGER'S TRAIT MODEL	SIEVER & DAVIS TRAITS AND NEURAL AYSTEMS	DEPUE, LENZENWEGER, & COLLEAGUES	LARA & AKISKAL'S INTEGRATIVE MODEL	FIVE FACTOR MODEL OF PERSONALITY
Basic Premise of Theory	Temperment is biologically driven and character influences the phenome.	PDs are variants on spectrum with Axis I disorders.	PDs emerge as phenotype of interaction of neurobehavioral system underlying traits.	Personality traits emerge from bidimensional expression of high or low fear and anger.	PDs are extremes of normal traits that can be identified by factor analysis.
Categories of Traits	Temperament <ol style="list-style-type: none"> (1) Novelty seeking (2) Harm avoidance (3) Reward dependence (4) Persistence Character <ol style="list-style-type: none"> (1) Self-directedness (2) Cooperativeness (3) Self-transcendence 	<ol style="list-style-type: none"> (1) Cognitive/perceptual organization (i.e., schizophrenia) (2) Impulsivity/aggressiveness (impulse control disorders) (3) Affective instability (mood disorders) (4) Anxiety/inhibition (anxiety disorders) 	Traits are derived from concepts common to many species: <ol style="list-style-type: none"> 1) Agenic extraversion 2) Neuroticism 3) Affiliation 4) Nonaffective constraint 5) Fear 	High fear is basis of anxiety disorders, depression and cluster CPD; low fear is basis of hyperactivity, mania, ADHD, and disruptive behaviors; high anger is basis for appetitive disorders, impulsivity, cluster BPD, and substance abuse; low anger is basis of inattention and unipolar depression.	Self-description can be reduced to 5 overarching constructs: <ol style="list-style-type: none"> (1) Neuroticism or negative affect (2) Extraversion or positive affect (3) Conscientiousness (4) Agreeableness (5) Openness to experience

(continued)

	CLONINGER'S TRAIT MODEL	SIEVER & DAVIS TRAITS AND NEURAL AYSTEMS	DEPUE, LENZENWEGER, & COLLEAGUES	LARA & AKISKAL'S INTEGRATIVE MODEL	FIVE FACTOR MODEL OF PERSONALITY
Impact of Biology	Temperament is related to limbic system and neurochemistry (e.g., novelty seeking). All PDs have immature character (since character is cognitive function that regulate goals and values) and development (low self-directedness and low cooperativeness) related to executive functioning.	Biomarkers are similar to the related Axis I disease (e.g., eye movement abnormalities in psychosis and cluster A) and neurotransmitters (e.g., serotonin for depression and affective instability).	Traits have associated neurotransmitters (e.g., norepinephrine in neuroticism and fear).	Fear is related to amygdala and GABA, serotonin norepinephrine. Anger is related to the nucleus acumbens and dopamine, glutamate, adenosine, and cortisol.	
Weaknesses of the Theory	It is the most widely studied but evidence is contradictory.	It has not been widely studied.	It has not been widely studied; traits do not relate to brain systems.	It is difficult to explain attachment and drive toward something.

PSYCHOTHERAPY OF PERSONALITY DISORDERS

The subjective distress, interpersonal impairment, and exhaustive consumption of mental health resources by individuals with PDs have rendered the continued generation, evaluation, and refinement of successful and cost-effective treatments for their condition a matter of great public health concern. The encouraging fact is that over the past years research has been mounting evidence for effective interventions for a malady previously considered untreatable. Meta-analyses (Leichsenring & Leibing, 2003; Perry, Baron, & Ianni, 1999) and systematic/literature reviews (Bateman & Fonagy, 2000; Binks, Fenton, McCarthy, Lee, Adams, & Duggan, 2007; McMain & Pos, 2007; Perry & Bond, 2000; Verheul & Herbrink, 2007) have shown that the principle form of treatment for personality disorders has been psychotherapy, with psychodynamic therapy taking a prominent role and cognitive-behavioral therapy and its variants showing rapid momentum and viability. Pharmacological treatment has also been incorporated as part of treatment, but as an appendage.

The different approaches taken by various studies to assess the efficacy of psychotherapeutic treatment pose a particular challenge in determining the meaningfulness of the studies' results. There exists variability in treatment protocols, treatment duration, follow-up periods, and representation of the different PDs in the samples. A systematic review by Verheul and Herbrink (2007) found that borderline, dependent, avoidant, and not-otherwise-specified personality disorders had the highest prevalence for investigation (20%–30%), while paranoid, obsessive-compulsive, and schizotypal personality disorders had a moderate rate of 10%, and schizoid, antisocial, narcissistic, and histrionic personalities had the lowest prevalence for investigation (0%–5%). There is also a lack of general agreement on which outcome measures to use, and decisions may depend on variables such as the setting of the study or the population (e.g., hospital vs. prison). Furthermore, certain measures have limitations and might exclude, exaggerate, or obscure important information, such as symptomatic or personality changes. Outcomes that have been measured in efficacy studies of intervention for personality disorders have included changes in symptoms, change in social functioning, change in self-harm behavior, recidivism rates, rates and duration of psychiatric hospitalization, global functioning, quality of life, and changes in personality (Bateman & Tyrer, 2004).

Meta-analyses have relied on effect sizes to facilitate outcome evaluation of different studies. As a common metric, it has been shown to be useful in addressing the question of what changes with psychotherapy. In 14 studies reviewed by Perry and Bond (2000), the largest effect sizes were shown for target complaints ($M = 1.80$; $SD = 0.48$), followed by depressive symptoms ($M = 1.79$; $SD = 0.45$), global functioning ($M = 1.64$; $SD = 0.76$), and general symptoms ($M = 1.10$; $SD = 0.55$). Moderate effect sizes ($M = 0.77$) were shown for domains of personality functioning (i.e., interpersonal problems, social adjustment). These results are consistent with the clinical observation that target symptoms, which induce one to come to therapy, tend to subside more quickly and earlier on in treatment, while underlying problems in personality functioning tend to take longer to improve.

Additionally, comparisons between active psychotherapy for PD groups and control conditions have shown greater effect sizes for improvement on both self-report and observer-rated measures for the treatment condition than for the latter. From 22 studies, Perry and Bond (2000) found that active psychotherapies yielded a mean effect size of 1.14 in self-report measures and 1.32 for observer-rated measures, while control conditions only yielded mean effect sizes of 0.31 for self-rated reports and 0.38 for observer-rated outcomes. An earlier study of outcome characteristics by Perry et al. (1999) revealed similar outcomes. For the active psychotherapies, mean effect size for self-report was 1.11 and 1.29 for observer-rated measures, whereas control conditions yielded a mean effect size of 0.25 for self-report measures and 0.50 for observer-rated measures.

Perry et al. (1999) found different patterns of change when comparing observer-rated and self-rated outcome measures. For the self-report measures, the mean effect size of 5 shorter-term therapies was significantly larger than that of 7 longer-term studies (1.38 vs. 0.92; $p = 0.02$). Furthermore, there was a negative correlation between duration and effect size for self-report outcomes and a positive correlation for observer-rated outcomes. Leichsenring and Leibing's meta-analysis (2003) confirms this trend. For psychodynamic therapy, which tends to be longer, the mean effect size for self-reported measures was 1.08, while observer-rated effect size was 1.79. For cognitive-behavior therapy, a generally shorter intervention, the mean effect size for self-rated instruments was 1.20, whereas observer-rated effect size was 0.87. This pattern suggests a "honeymoon effect" in the shorter-term treatments. The fact that this trend was not apparent in the observer-rated measures may suggest

that early improvement represents state rather than trait changes and that traits require more time to change.

Rate of recovery has been another way of measuring effectiveness of psychotherapeutic treatment. Studies have shown a relationship between remission from full criteria for a personality disorder and duration of treatment. Four studies examined by Perry et al. (1999) revealed that 52% of patients with Cluster B and C personality remitted after approximately 1.3 years of treatment. Treatment included both individual and group formats, provided on a once- or twice-weekly basis. A model from these data was generated to predict remission rate per year of therapy. Although considered only hypothetical and not statistically significant, the model was compared to a naturalistic study of the remission of BPD and revealed a sevenfold rate larger than the naturalistic study (25.8% remission per year vs. 3.7% per year).

Verheul and Herbrink (2007) reviewed the empirical evidence for the efficacy of four different psychotherapy formats and settings (i.e., group therapy, outpatient individual psychotherapy, day hospital psychotherapy [where the patients come in for several hours during the day and participate in various therapeutic modalities, such as individual therapy, group therapy, and milieu activities, and then go home at the end of the day], and inpatient psychotherapy) and found that various psychotherapeutic treatments decreased symptoms and personality pathology and brought about improvements in social and occupational functioning in Cluster A, B, and C and not-otherwise-specified patients. This was most notable for outpatient individual psychotherapies employing cognitive-behavioral or psychodynamic approaches. Other effective interventions included long-term outpatient psychodynamic group therapy, short-term psychodynamic group therapy in a day hospital, and inpatient psychodynamic psychotherapy with varying treatment duration.

McMain and Pos (2007) reviewed randomized controlled and quasi-experimental trials on treatment for Axis II disorders that were published between January 2003 and October 2006. Although they found an increase in the number of well-controlled trials and longitudinal studies, the majority of the collected studies continued to focus on treatment for BPD. Studies on BPD that compared dialectical behavior therapy to treatment by experts or to treatment-as-usual controls found that the DBT groups were associated with decreased suicide attempts, fewer hospitalizations and emergency room visits, better retention rates, and decreased impulsive behaviors (Linehan et al., 2006; Verheul, van den Bosch, Koeter, de Ridder, Stijnen, & van den Brink,

2003). Adaptations of dialectical behavior therapy to inpatient settings and brief intensive outpatient programs for BPD also yielded reduced levels of depression, hopelessness, anxiety, and global psychopathology (Bohus et al., 2004; Kroger et al., 2006; McQuillan, Nicastro, Guenot, Girard, Lissner, & Ferrero, 2005).

Other factors affecting the treatment of personality disorders include level of disturbance, comorbidity, therapeutic alliance, motivation for treatment, and theoretical coherence and fidelity to practice. In studies comparing PD subjects with non-PD subjects, those without personality disorders improved to a greater extent than those with PDs (Diguer, Barber, & Luborsky, 1993; Fahy, Eisler, & Russell, 1993; Hardy, Barkham, Shapiro, Stiles, Rees, & Reynolds, 1995; Karterud, Vaglum, Friis, Irion, Johns, & Vaglum, 1992; Leichsenring & Leibing 2003). In their review, Perry et al. (1999) found that those with Cluster C diagnoses showed greater improvement than those with BPD, who in turn improved more than schizotypal patients. Patients with ASPD also appear to have poorer outcomes, except when suffering from comorbid depression. This points not only to the impact of symptom distress as a motivational factor in treatment but also to the modulating effect of the ability for attachment (Gerstley, McLellan, Alterman, Woody, Luborsky, & Prout, 1989; Woody, McLellan, Luborsky, & O'Brien, 1985).

Studies have shown that the quality of the therapeutic alliance is associated with treatment compliance and outcome. Spinhoven, Giesen-Bloo, van Dyck, Kooiman, and Arntz (2007) found that therapist ratings of alliance early in treatment predicted outcome, and patients' experience of growth of the therapeutic relationship early in treatment predicted reduction of symptoms. The working alliance has also served as a mediating factor in the receptivity to certain therapeutic interventions. Interpretive interventions, particularly transference interpretations, in which therapists attempt to elucidate underlying processes that alleviate discomfort or signal changes in topic contents, are "high-risk, high gain" interventions (Gabbard et al., 1994), especially in work with patients with PDs. The therapeutic venture can be greatly enriched or made aversive by such methods. Bond, Banon, and Grenier (1998) found that in the presence of a strong therapeutic alliance, transference interpretation enhanced work by promoting emotional elaboration and increased insight, whereas its intervention was poorly tolerated in a tenuous alliance. In the latter case, the fragile patient will feel defensive and criticized, prompting reversion to maladaptive, rigid, and primitive defenses, furthering the chasm between the patient and the therapist. More supportive strate-

gies that employ techniques such as acknowledgement, reflection, clarification, and validation are indicated for more fragile and labile patients. Such techniques can prepare the way for more exploratory methods.

DIALECTICAL BEHAVIOR THERAPY

Dialectical behavior therapy (DBT) is a cognitive-behavioral intervention that was developed by Marsha Linehan in the 1980s as a treatment for patients with BPD, notably those with suicidal and self-injurious tendencies (Linehan, 1993a). DBT derives its organizing framework from the philosophical worldview of dialectics, which engages the exchange between opposing assertions (i.e., thesis and antithesis) in an attempt to synthesize the two to produce resolution, growth, and development. Also embedded in this structure of polarities are the theoretical positions of behavioral science (i.e., learning principles), with its emphasis on change, and Zen mindfulness practice, which underscores the need for acceptance and tolerance. Early in her clinical training and work with parasuicidal patients, Linehan observed the importance of balancing the need for change and acceptance/validation of the patient. An overemphasis on promoting change tended to elicit protests from the patient, who experienced this push as an invalidation of his or her responses and private experience. Likewise, a therapeutic strategy based solely on validation and unconditional acceptance prompted protests, as patients perceived it as a disregard for their need to change and seek a sense of hope.

DBT assumes a systemic view of reality, in which the nature and function of parts are fully appreciated and understood in relation to its whole. BPD is understood as resulting from a combination of systematic dysfunctions, primarily with the emotion regulation system, owing to biological vulnerabilities, and an invalidating environment that repeatedly negates or inappropriately responds to private experiences (Linehan, 1993a; Miller, Rathus, & Linehan, 2007). This is referred to as the biosocial theory.

DBT incorporates four concurrent components to treatment: individual therapy, group skills training, patient-therapist telephone consultation, and team consultation for therapists. Patients attend individual therapy sessions with a primary therapist at least once a week for 50–60 minutes. Longer sessions (“double sessions”) lasting 90–110 minutes can also be held for patients who have not yet developed the capacity to open up and emotionally close during the allotted time in the shorter sessions. The individual therapist structures

the sessions according to a hierarchy of primary targets. Diary cards aid in setting the agenda. Life-threatening behaviors (i.e., suicidal behaviors) are addressed first, followed by therapy-interfering behaviors (e.g., tardiness to sessions, incomplete homework). Quality-of-life issues are then addressed, along with increasing behavioral skills.

DBT skills training takes place in a psychoeducational group context. The group sessions are conducted weekly for 2–2.5 hours. They are aimed at facilitating behavior change through direct instruction from a skills training manual (Linehan, 1993b), modeling of behaviors, rehearsals, prompting, shaping through successive approximation, and positive reinforcements. Four skills training modules are covered: mindfulness, distress tolerance, emotion regulation, and interpersonal effectiveness. Group time is also used to assign and review homework.

DBT makes use of patient-therapist telephone consultation between sessions to encourage and build the confidence of BPD patients to appropriately seek help during crisis situations and to increase generalization of behavior skills. Telephone consultations are limited to skills coaching and relationship repair. Patients are informed of the 24-hour rule, which states that they cannot call the therapist for 24 hours after engaging in parasuicidal behavior. This is to discourage reinforcement of maladaptive behaviors. Rather, they are encouraged to call before engaging in self-injurious behavior, so that the therapist can coach and aid them in adaptive problem solving.

To provide effective and optimal treatment, prevent therapist burnout, and preserve professional and clinical competence, DBT therapists are required to attend weekly case consultation meetings with other DBT therapists. The consultation meetings provide therapists with support, a forum in which they can discuss problems they are experiencing with their patients, and a means of recalling DBT principles and treatment hierarchy.

As previously mentioned, the DBT skills training is aimed at remediating behavior skills deficits in individuals with BPD. This includes changing emotional and thinking patterns that contribute to their distress. This is done through four modules aimed at decreasing interpersonal, emotional, behavioral, cognitive, and self-dysregulation. The first module, core mindfulness skills, integrates Zen meditation exercises that are compatible with Western contemplative and other Eastern meditation practices. It teaches three “what” skills aimed at fostering a lifestyle of participation with awareness and three “how” skills that promote non-

judgmental thinking. The second module, distress tolerance skills, focuses on increasing the patient's capacity to tolerate and survive crises and accept reality as it is in the moment. Crisis survival strategies include distracting, self-soothing, relaxation/imagery, and identification of pros and cons. Acceptance strategies are also taught. Emotion regulation, the third module, provides instructions on regulating emotional intensity and lability, often characteristic of borderline individuals. Skills include identifying and labeling emotions, identifying obstacles to managing affect, reducing vulnerability to emotional reactivity through basic self-care, increasing the occurrence of daily positive experiences, and engaging in opposite behavioral-expressive actions. The fourth module involves skills training in interpersonal effectiveness. Patients are taught ways to assert their needs, say no, and manage interpersonal conflicts.

DBT employs various treatment strategies. For a more comprehensive description of those techniques, consult Linehan's book and manual (1993a, 1993b). As previously described, diary cards are used to monitor the occurrence of target behaviors (i.e., self-harm, suicidal behaviors, substance use, and other behaviors that the patient and therapist decide are important to monitor). They also provide a means of tracking the frequency of skills utilization. The diary cards are reviewed at the beginning of the therapy session and can set the session agenda. They are a helpful means of communicating to the therapist, particularly if the patient is not able to recall events of the past week or is ashamed of verbally disclosing target behaviors. Once target behaviors are identified, a behavioral chain analysis can be used to explore, in greater detail, the chain of events leading to those behaviors. The therapist and patient identify the antecedents (i.e., what was happening at the time the problem started?), the patient's behavioral response (i.e., what was the patient thinking, feeling, doing, and imagining?), and the consequences of the patient's behaviors (i.e., what reinforced the behaviors?). The tedious process involved in conducting a chain analysis can serve as an aversive consequence to maladaptive behaviors. Validation is another core strategy of DBT. It is a counterpoint to change strategies and conveys to the patient "that her behavior makes sense and is understandable -in the current context" (Linehan 1993a, p. 221). When validating, it is essential to first actively observe the patient's thoughts, feelings, and actions; reflect back to the patient in a nonjudgmental fashion her thoughts, feelings, and behaviors; and then use direct validation (i.e., pointing out the "wisdom" or adaptive nature of the behavior in the specific context).

Randomized controlled trials have been conducted to test the effectiveness of DBT on suicidal women with

borderline personality disorder (Linehan, Armstrong, Suarez, Allmon, & Heard, 1991; Linehan, Heard, & Armstrong, 1993; Linehan, Tutek, Heard, & Armstrong, 1994, Linehan et al., 2006). In the original study, Linehan et al. (1991) compared 1-year comprehensive DBT treatment to community-based "treatment as usual" and found that those who received DBT exhibited significant reductions in parasuicidal behaviors, had better treatment retention, and had fewer inpatient hospital stays than the treatment-as-usual subjects. These results were largely maintained throughout the 1-year post-treatment follow-up. DBT subjects showed significantly fewer parasuicidal behaviors, less anger, and better self-reported social adjustment than treatment-as-usual subjects during the initial 6-month follow-up, and they had fewer days spent in the psychiatric unit and better interviewer-rated social adjustment during the final 6 months of follow-up (Linehan et al., 1993). Compared to community treatment by experts, DBT has also been shown to yield fewer suicide attempts, fewer emergency room visits and psychiatric hospitalizations, lower medical risks associated with suicidal and self-injurious acts, and better treatment retention rates (Linehan et al., 2006). Both conditions have shown significant improvement on depression, reason for living, and suicide ideation. Other randomized controlled studies have demonstrated the effectiveness of DBT in treating women with BPD and some form of substance dependence/abuse (Linehan, Schmidt, Dimeff, Craft, Kanter, & Comtois, 1999; Linehan et al., 2002; van den Bosch, Koeter, Stijnen, Verheul, & van den Brink, 2005; Verheul, Schippers, & van den Brink, 2002; Verheul et al., 2003), females with eating disorders (Safer, Telch, & Agras, 2001; Telch, Agras, & Linehan, 2001), BPD and depressed women recruited from the Veterans Health Administration (Koons et al., 2001), and depressed individuals age 60 and older (Lynch, Morse, Mendelson, & Robins, 2003). Adaptations of DBT in inpatient settings have also revealed its effectiveness in improving depression, anxiety, interpersonal functioning, social adjustment, global psychopathology, and self-mutilating behaviors (Bohus et al., 2004; Kroger et al., 2006). DBT has also been adapted to treat suicidal adolescents (Katz, Cox, Gunasekara, & Miller, 2004; Miller et al., 2007; Rathus & Miller, 2002).

COGNITIVE THERAPY

Cognitive therapy was developed by Aaron T. Beck in the 1960s, originally as a treatment for depression (A. T. Beck, 1964). It focuses on the interactions between thoughts, feelings, and behaviors, with an em-

phasis on the modulating effect of cognitions, in the form of automatic thoughts, assumptions/attitudes, and core beliefs (schemas). Central to its perspective is the assumption that humans are equipped with an information-processing system that functions to organize (i.e., perceive, store, recollect, and interpret) raw data, such as stimuli or events, and shape affective experiences and behavioral responses (Pretzer & Beck, 2005; A. T. Beck, Freeman, Davis, et al., 2004). In the course of human evolution, natural selection has preserved certain predispositions within the information-processing system that worked toward the goals of survival and reproduction. For example, in more primitive times, when the threat of wild animals and/or invading clans was much more common, a bias toward hypervigilance and exaggeration of perceived threat provided a “good fit” and promoted survival. While our society has shifted from a primitive one to a technologically advanced one, our inherited predispositions may not have kept abreast of the changes of modernity, thus creating a poor fit. Psychological disturbances can be conceptualized as stemming from a residual bias toward more primitive strategies, of which personality disorders may reflect a more pervasive and exaggerated reliance. Furthermore, psychopathology can be characterized by its propensity for misperceptions, misinterpretations, and dysfunctional thought patterns, which give rise to persistent, inflexible, and maladaptive interpersonal strategies. The cognitive model also recognizes the influence of constitutional defects, trauma, and undesirable social learning in the formation of schemas and the phenotype of personality disorders.

As previously mentioned, cognitive therapy systematically examines three levels of cognitive structure in the course of treatment: (1) automatic thoughts; (2) attitudes, assumptions, and rules; and (3) core beliefs, or schemas (J. S. Beck, 1995). The process is analogous to peeling an onion down to its core. The most readily accessible level of cognition is the automatic thought, a spontaneous stream of thought or evaluative response to a situation. It can be elicited by the simple question “What was going on in your mind at the time when your mood changed?” The validity and utility of the automatic thoughts are then evaluated through Socratic questioning. Systematic errors in reasoning are also uncovered. Such errors, often referred to as “cognitive distortions,” can include, for example, dichotomous thinking, overgeneralization, imperatives, personalization, catastrophizing, and disqualifying the positive (J. S. Beck, 1995; Pretzer & Beck, 2005). Our automatic thoughts are generally buttressed by unarticulated assumptions, attitudes, or rules by which we operate.

Such implicit, intermediate beliefs can be discovered through the use of a variation of the Socratic questioning method called the downward arrow technique, which follows the logical progression of an automatic thought in an “as if” mode. In other words, the therapist continues to ask what it means to the patient if such a thought were true. Intermediate beliefs are generally expressed in the form of conditional statements (e.g., “If I do not pass the exam, then I must be stupid”), premises (e.g., “All suffering is bad; weakness is not valued”), or self-injunctions (e.g., “Friends never let each other down”). Automatic thoughts and intermediate beliefs, to a lesser extent, are malleable. The least malleable or readily recognizable level of cognition is the core belief. It is our most central form of self-appraisal and consists of a network of various schemas and sub-schemas that serve as the framework for organizing raw data and attaching significance to experiences/situations and subsequently shape behavioral and emotional responses. Like individuals with symptom syndromes (i.e., Axis I), those with PDs possess schemas that are idiosyncratic, hypervalent, and prepotent (A. T. Beck, 1964; A. T. Beck et al., 2004). That is, the particular thought content and processes characteristic of their pathology tend to be activated at a lower threshold and tend to displace or inhibit more adaptive schemas. However, unlike the symptom syndromes, in which the maladaptive schemas operate only during a symptomatic phase, persons with PDs have schemas that function on a continuous basis. Beck organizes core beliefs into two general categories (J. S. Beck, 1995): helpless core beliefs and unlovable core beliefs.

The following are descriptions of the cognitive patterns of the different personality disorders, as characterized by the American Psychiatric Association (2000) and Beck (A. T. Beck et al., 2004).

Cluster A

- **Paranoid**—Characterized by mistrust and suspicion of others. Core beliefs: “I am vulnerable,” “Others are intent on hurting or manipulating me.” Assumptions: “If people interact with me, then they must want something from me,” “There is always a catch,” “The world is a dangerous place.” Instrumental belief/interpersonal strategies: “Trust no one,” “Always be on the lookout.”
- **Schizoid**—Characterized by social isolation and restriction of emotional expression. Core beliefs: “I am alone,” “Relationships are a hindrance to my freedom.” Assumption: “I’ll be happy if I don’t get too close to others.” Instrumental belief/interpersonal strategies: “Keep at a distance,” “Don’t get involved.”

- **Schizotypal**—Characterized by discomfort in relationships, cognitive or perceptual distortions, and eccentric behavior. Core beliefs: “I am different,” “I am defective.” Assumptions: “If people see that I am different, then they will notice me,” “If I have special powers, then that makes me important.” Instrumental belief/interpersonal strategies: “Keep away from others,” “Be different,” “Watch out for others trying to get you.”

Cluster B

- **Antisocial**—Characterized by exploitation of others or disregard for established rules or societal norms. Core beliefs: “I’m above the law,” “I’m looking out for number one.” Assumptions: “It’s a dog-eat-dog world,” “If you don’t take advantage of others, then they’ll take advantage of you.” Instrumental belief/interpersonal strategies: “I’ll get what I want, whatever cost,” “Get them before they get you.”
- **Borderline**—Characterized by unstable interpersonal relationships, sense of self, affectivity, and impulse control. Core beliefs: “I am unlovable,” “I am vulnerable and weak,” “Others are malevolent and can’t be trusted.” Assumptions: “The moment I begin to trust others, I will be hurt and then abandoned,” “The worst thing is to be abandoned.” Instrumental belief/interpersonal strategies: “Threaten others and punish myself whenever I experience pain or rejection,” “Escape the pain through suicide.”
- **Histrionic**—Characterized by excessive expressiveness. Core beliefs: “I am unattractive,” “I am unlovable.” Assumption: “If I’m not the center of attention, then I am nothing.” Instrumental belief/interpersonal strategies: “Show your feelings,” “Be the life of the party.”
- **Narcissistic**—Characterized by grandiosity and lack of empathy. Core beliefs: “I’m unlovable,” “I’m inadequate,” “I’m entitled to privileges because I am superior to others.” Assumptions: “I am great; therefore others should serve me,” “If I’m not the best, then I’m nothing.” Instrumental belief/interpersonal strategy: “Compete and show others you are on top.”

Cluster C

- **Avoidant**—Characterized by social inhibition, fear of negative appraisals, and feelings of inadequacy. Core beliefs: “I am unlovable,” “I am incompetent,” “I am not good enough.” Assumptions: “Once people get close to me, they will discover my weaknesses

and then reject me,” “If I don’t succeed, then I am a failure.” Instrumental belief/interpersonal strategies: “It’s best to avoid challenges so that you don’t fail or get disappointed,” “Lay low.”

- **Dependent**—Characterized by submission and clingy behavior. Core beliefs: “I am weak,” “I am helpless.” Assumption: “The only way I can be happy and complete is if I am always with someone who will take care of me.” Instrumental belief/interpersonal strategy: “Do what he or she asks so he or she won’t leave me.”
- **Obsessive-compulsive**—Characterized by an excessive need for control, orderliness, and perfection. Core beliefs: “I’m out of control,” “I’m disorganized.” Assumptions: “If I don’t have order, then I have chaos,” “The only way to live is perfection.” Instrumental belief/interpersonal strategy: “You should always try hard and do well.”

Cognitive therapy employs a variety of techniques, some of which are common to other cognitive-behavioral interventions and psychodynamic methods. Although cognitive therapy is manualized, it is important to bear in mind the presence of PDs, and to modify the treatment approach to account for the complexity that PDs add to the patient’s clinical presentation and trajectory of outcome. Like its other cognitive-behavioral therapy (CBT) kindred, cognitive therapy relies on “collaborative empiricism” (Beck et al., 1979, cited in Pretzer & Beck, 2005), in which the patient actively participates in gaining understanding of his or her own problems and the factors contributing to them; testing the validity of thoughts, assumptions, and core beliefs; and completing homework and behavioral experiments that challenge old patterns and lead to cognitive, behavioral, and affective changes. The dysfunctional thought record is a basic tool for monitoring a patient’s thoughts, feelings, and actions (Beck et al., 1979, cited in J.S. Beck, 1995, p. 125). Formatted similarly to Ellis’s ABC model used in rational-emotive behavior therapy, the dysfunctional thought record tracks activating events/situations, automatic thoughts/beliefs, emotional consequences, adaptive responses/disputes to dysfunctional thoughts, and outcomes. Socratic questioning and guided discovery are used by the therapist to uncover underlying beliefs or schemas, and they are followed by an examination of the evidence for and against such conclusions. The therapist also aids the patient in reframing, or generating alternative explanations for, events that have triggered faulty thinking. Another effective tool is the continuum method, which asks patients to rate themselves between 0 and 100 on a belief scale, which consists of a global

belief broken down into basic and differing gradations. This is useful for modifying global, biased, and extreme thinking. Other behavioral methods include modeling, rehearsing, role-playing, graded tasks, and imagery.

The bidirectional effects of the patient and therapist's relational strategies may interfere with their therapeutic collaboration. PD patients commonly experience transference. A central psychodynamic concept, it is conceptualized by the cognitive model as an overgeneralization of the individual's negative expectancies and distorted beliefs. Therapists must be aware of its occurrence and immediately address the misconceptions and expectancies that hinder therapeutic progress. Likewise, a therapist can experience countertransference, particularly feelings of frustration, anger, and discouragement, when working with difficult patients. To minimize these problems, therapists are encouraged to seek consultation and supervision, during which time they can also examine their own automatic thoughts, assumptions, and core beliefs/schemas.

Jeffery Young (1990) is another major contributor to the cognitive model. His schema-focused cognitive therapy has its conceptual foundation in the Beckian model and retains most of its approach to therapy. However, Young's model places less emphasis on guided discovery and more on confrontation. Also, therapy tends to be lengthier, and more focused on exploring and overcoming cognitive and behavioral avoidance and examining early maladaptive schemas and the emotions related to those schemas.

Studies indicating the efficacy of cognitive therapies for PD have been emerging. An open study of cognitive therapy for antisocial and borderline personality disorder found improvements in cognitive and behavioral patterns after 10 weeks of treatment (Davidson & Tyrer, 1996, cited in Bateman & Fonagy, 2000). In the study by Weinberg, Gunderson, Hennen, and Cutter (2006), 30 female BPD patients were randomly assigned to either Manual Assisted Cognitive Treatment (MACT) plus treatment as usual (TAU) or TAU only. The findings showed MACT to be associated with significant decrease in deliberate self-harm frequency at the end of treatment. Furthermore, gains were maintained at 6-month follow-up for deliberate self-harm frequency and severity. MACT, however, did not affect suicide tendencies or time to repetition of deliberate self-harm. The study also found an association between decrease in deliberate self-harm frequency and concurrent treatments at post-treatment and at follow-up; however, it was much less than the contribution of MACT. The Borderline Personality Disorder Study of Cognitive Therapy randomized controlled trial (K. Davidson et al., 2006)

also compared CBT plus TAU to stand-alone TAU for the treatment of BPD. Both conditions yielded reductions in suicidal behavior, accident and emergency services, and inpatient psychiatric hospitalization over the 2-year study period. However, the addition of CBT contributed to a significant reduction in the mean number of suicidal acts. Also, significant differences were found between CBT plus TAU and TAU alone in psychiatric symptom distress, dysfunctional core beliefs, and state anxiety, in favor of CBT plus TAU. Giesen-Bloo et al. (2006) conducted a randomized controlled trial comparing schema-focused therapy, a form of cognitive therapy, with transference-focused therapy (TFP), a psychodynamically based treatment, for the treatment of BPD patients. The study found that 3 years of either condition yielded significant improvements in BPD manifestation, general psychopathologic dysfunctions, personality concepts, and quality of life. However, participants in schema-focused therapy showed greater changes than those in TFP in the first three aforementioned domains. Lastly, attrition rate for schema-focused therapy was significantly lower than for TFP. In another randomized controlled trial, Emmelkamp, Benner, Kuipers, Feiertag, Koster, and Apeldoorn (2006) compared the effectiveness of outpatient CBT with brief dynamic therapy for AVPD. The study also included a wait-list control group. The effect size of CBT was large on five out of six measures (i.e., anxiety symptoms, avoidant personality, social phobia, avoidance, and obsessive-compulsive scale). Analyses of variance indicated that CBT was significantly superior to its comparison treatment condition on all primary measures. Gains were maintained for both CBT and brief dynamic therapy groups at follow-up; however, only 9% of the CBT group still met criteria for AVPD, while 36% of those in brief dynamic therapy met criteria at follow-up. Another study (Svartberg, Stiles, & Seltzer, 2004) compared the effectiveness of short-term dynamic therapy with cognitive therapy for Cluster C personality disorders and found that both conditions yielded statistically significant improvements on all measures during the treatment period and at 2-year follow-up. Also, both conditions produced large effect sizes (i.e., 1.07 for short-term dynamic psychotherapy and 1.29 for cognitive therapy) for interpersonal problems.

PSYCHOANALYSIS/PSYCHODYNAMIC PSYCHOTHERAPY

Psychoanalysis is a branch of psychology concerned with investigating the underlying source of one's men-

tal state and behavior. Developed by Sigmund Freud in the late 19th and early 20th centuries, it consists of specific techniques (e.g., free association) aimed at uncovering the nature and structure of the mind, particularly the unconscious realm; a therapeutic approach based on that understanding; and a model of psychological development based on investigative and clinical experience (Bateman & Holmes, 2003, pp. 4, 17). Distinctive to this approach is the centrality of early childhood experiences on the development of the psyche and present relationships, the concept of transference, the role of unconscious experiences in the form of drives or desires, and the use of resistance and other defenses. Psychoanalysis, along with its variants, fundamentally aims at engendering self-understanding and structural changes in personality associated with pathological symptoms and traits. During and since the time of Freud, the psychoanalytic movement experienced revisions of ideas, divergence in focus, and the development of sub-branches with varied conceptualizations of presenting problems and therapeutic techniques. One can view this phenomenon metaphorically as the father of psychoanalysis giving birth to children of different characteristics, who eventually seek to achieve a sense of autonomy while still retaining their familial roots (Bateman & Holmes, 2003, p. 17). The frequency of therapy has been an accepted way of differentiating the parent (i.e., psychoanalysis) from his children (i.e., psychodynamic psychotherapy). A hallmark of psychoanalysis has been the occurrence of more than three sessions per week. Three or fewer sessions is generally characteristic of psychodynamic psychotherapy. Bateman and Holmes (2003) take a provisional position that sees “psychoanalytic therapy as a spectrum from ‘full’ psychoanalysis to psychoanalytic psychotherapy, from the use of methods that are expressive to those that are supportive, from interpretation to ‘holding’” (p. 17). Others have espoused the position of a “common ground” (Wallerstein, 1992, cited in Bateman & Holmes, 2003, p. 18) in clinical practice, characterized by a focus on “empathy, holding, interpretation, defence, analysis of transference and resistance.” Of classical psychoanalysis’s offspring, the most prominent models are object relations, ego psychology, self-psychology, and attachment theory.

The section on theoretical psychodynamic models for personality disorders already provided a description of how the different PD clusters are conceptualized. What follows, then, will be brief descriptions of select psychoanalytically oriented and psychodynamic psychotherapeutic approaches (i.e., transference-focused therapy, supportive-expressive psychotherapy, and men-

talization-based therapy) and the results of studies using those methods.

Transference-focused therapy is a manualized therapy for patients with severe personality disorders. The approach is informed by object relations theory, more specifically, Kernberg’s object relations model of BPD. Presumably, the relationship between the patient and therapist eventually reflects a reenactment or recapitulation of the maladaptive interpersonal patterns that are recurrent in the patient’s relationships. As such, therapy explores the here-and-now interactions between the patient and therapist to provide an understanding of and modify the conflictual and pathogenic aspects of the patient’s internal object relations (Kernberg & Caligor, 2005). A twice-weekly therapy based on psychoanalytic principles, TFP aims to accomplish three tasks through the use of specific strategies. First, the therapist identifies the polarized (i.e., persecutory/idealized) or conflictual internal object relation and then explicates its representation in the current transference, pointing out, specifically, the self- and object representations and the affective-laden themes that link them. Next, the therapist elucidates the relationship between the dominant object relation in the transference and the split-off counterpart that is activated at other times (Kernberg & Caligor, 2005). The therapist employs clarification, confrontation, interpretation, systematic transference analysis, and technical neutrality in bringing about the patient’s gradual integration of the conflictual internal object relations (Clarkin, Foelsch, Levy, Hull, Delaney, & Kernberg, 2001; Kernberg & Caligor, 2005).

A 12-month preliminary study using TFP with female BPD patients conducted by Clarkin and colleagues (2001) found a significant reduction in suicide attempts during the treatment year compared to the pre-treatment year and a significant decrease in psychiatric hospitalizations and number of days of hospitalization during the treatment year. Limitations to this study included the lack of a control group, the homogeneity of the PD, and the exclusion of more realistic comorbid conditions (i.e., alcohol/substance dependence). Using a randomized controlled trial design, Clarkin et al. (2004, 2007) compared TFP with DBT and supportive psychotherapy during a 1-year outpatient treatment study of patients with BPD. Six domains were measured; suicidality, aggression, and impulsivity were primary domains, and anxiety, depression, and social adjustment were secondary domains. Results showed that all three treatments were associated with positive changes in depression, anxiety, global functioning, and social adjustment. With regards to primary domains, TFP was associated with improvements in suicidality, anger, Bar-

ratt Factor 2 impulsivity, irritability, verbal assault, and direct assault. DBT was associated with improvement in suicidality only, and supportive treatment was associated with improvements in anger and Barratt Factor 3 impulsivity. The study suggests that symptom change and the development of adaptive constraint and regulative mechanisms can be brought about through different means. TFP facilitates these changes through the integration of conflicted and affect-laden self and other representations, whereas DBT provides a validating environment while teaching emotion regulation skills. In another randomized controlled study, Levy et al. (2006) assessed attachment organization and reflective function as putative mechanisms of change in a yearlong TFP, DBT, or supportive treatment for BPD patients. The results showed increased secure attachment, narrative coherence, and reflective functioning over the course of treatment for those who received TFP. No changes in resolution of loss or trauma were found across any of the treatments.

Supportive-expressive psychotherapy (SEP) is another psychoanalytically informed approach that incorporates both analytic and supportive elements. SEP effects therapeutic changes by facilitating increased understanding of the symptoms and the related core conflictual relationship themes that affect the patient's functioning by fostering a helping alliance, and by promoting internalization, maintenance, and generalization of the treatment gains (Luborksy, 1984). Self-understanding is attained through expressive techniques, whereby the therapist promotes the expression of thoughts and feelings, from which is recognized the patient's wish, needs, intentions, and conflictual relationship patterns as re-experienced in the context of the therapeutic relationship in the here and now. The therapist then provides an evaluation and response in the form of interpretations or confrontation. The helping or therapeutic alliance is achieved through supportive conditions, as in a positive attachment between the patient and therapist, structural procedures (i.e., explicit agreements, goals, regular sessions), and an empathic and attuned posture assumed by the therapist. Supportive techniques also include clarification, validation, and reflection. SEP affords the therapist the flexibility to adjust between exploratory/interpretive and supportive methods.

A study by Blatt and Shahar (2004) used data from the Menninger Psychotherapy Research Project (Wallerstein, 1986, cited in Blatt & Shahar, 2004) to examine what differences in outcome exist between psychoanalysis and SEP. The study found that psychoanalysis and SEP involve different mechanisms of therapeutic change

that differentially interact with the patient's pretreatment characteristics. Introjective patients, those who are emotionally and socially detached and who tend to have an avoidant or dismissive attachment style, do better in psychoanalysis. The study revealed that psychoanalysis contributes to an increase in their adaptive interpersonal capacities while reducing their maladaptive interpersonal capacities. Introjective patients benefit from interpretations and therapeutic modes that engage their associative processes and increase referential activity. SEP found greater success with anaclitic patients, affectively labile individuals who possess greater preoccupation with relatedness and who tend to have a preoccupied insecure attachment style. The study found that SEP decreased maladaptive interpersonal capacities in anaclitic patients. This is because SEP provides the emotional containment they need through less referential and associative activities. In an open trial, Barber, Morse, Krakauer, Chittams, and Crits-Christoph (1997) examined the effects of time-limited SEP on patients with obsessive-compulsive and avoidant personality disorders. Overall, both groups demonstrated significant improvements on measures of personality, global functioning, anxiety, depression, and interpersonal problems. However, more OCPD patient remitted by the end of treatment than AVPD (i.e., 15.4% OCPD still met Axis II criteria vs. 38.5% AVPD). Also, OCPD patients tended to remain in treatment longer than AVPD patients. The study had several limitations, namely, its lack of control groups, the small sample size, and co-occurrence of Axis I disorders and symptomatology. In a randomized controlled trial, Vinnars, Barber, Noren, Gallop, and Weinryb (2005) compared manualized SEP with non-manualized community-delivered psychodynamic therapy for PD patients. Results showed that SEP was not superior to its comparison condition. The non-manualized community-delivered psychodynamic therapy was conducted by expert clinicians, most of whom tended toward a psychoanalytic approach. Both treatment groups yielded a reduction in the severity of personality disorders, a decrease in severity of psychiatric symptoms, and improvements in global functioning. There were no significant differences between the treatment groups; however, effect sizes indicated differential mechanisms of change between treatments. Community-delivered psychodynamic therapy tended to effect greater changes in psychiatric symptoms, whereas SEP focused on long-standing character traits. At post-treatment, 34% of the patients no longer met criteria for a personality disorder diagnosis, and at the 1-year follow-up, 47% no longer met criteria. Improvements in personality pathology were not found to be

mostly accounted for by improvement in co-occurring Axis I symptoms. Results also revealed the greatest improvement in patients with PDs not otherwise specified and the least improvement in Cluster C patients.

Mentalization-based treatment (MBT), developed by Fonagy and his colleagues (Allen & Fonagy, 2006; Bateman & Fonagy, 2004; Fonagy, Gergely, Jurist, & Target, 2002), is another psychoanalytically oriented approach to treatment of PDs, namely, BPD. Conceptually rooted in psychoanalytic object relations theory, developmental psychology, attachment theory, and the philosophical traditions of German idealism and theory of mind, which posit the notion of self-knowledge through others, MBT aims to promote the capacity to understand one's behavior, as well as that of others, in terms of intentional mental states, such as thoughts, feelings, needs, desires, and goals. Mentalization involves not only cognitive processes, but also affect discovery and regulation (Fonagy et al., 2002). Mentalization is integral to the development of the psychological and agentive self, our representational systems (i.e., our inner self), our adaptive interpersonal interactions, and the strengthening of resilience, an essential attribute for buffering the effects of various kinds of trauma (Allen, 2005). One's mentalizing capacity is cultivated in secure attachment relationships (e.g., caregiver/child, therapist/patient), in which a benign, mature, and attuned mind mirrors the subject's affect in a congruent and marked manner. Thus, MBT centers around the goals of fostering the reflective capacities of the patient in order that he or she can achieve an understanding of his or her affective experience, a coherent sense of self, stable internal representations, and the capacity to form secure relationships (Bateman & Fonagy, 2004). Techniques in the service of this aim include identifying, exploring, and praising positive mentalizing; encouraging genuine curiosity, pausing and challenging failed mentalization; exploring underlying feeling states; applying hypotheticals and counterfactuals; and mentalizing the transference (Bateman & Fonagy, 2006; Fearon et al., 2006). MBT focuses on understanding and labeling the patient's here-and-now mental state rather than on symbolic interpretation or uncovering unconscious conflict. At the core of this therapeutic endeavor is a relational stance that "reflects an expectation that one's own thinking and feeling may be enlightened, enriched, and changed by learning about the mental states of other people" (Fearon et al., 2006, p. 214).

Studies by Bateman and Fonagy (1999, 2001, 2008) have produced promising empirical evidence for mentalization-based psychoanalytic treatment. In their randomized controlled study that compared the effec-

tiveness of a psychoanalytically oriented partial hospitalization program with that of standard psychiatric care (control group) for the treatment of BPD, patients in the treatment group showed statistically significant reductions on all outcome measures compared to the control group—that is, on frequency of suicide attempts and self-mutilating behaviors, amount and length of inpatient admissions, psychopharmacological use, self-reported depression, anxiety, general symptom distress, interpersonal problems, and social adjustment. Furthermore, decreases in suicidal and self-injurious behaviors, inpatient admissions, depression, and interpersonal and social problems began at 6 months and were maintained at 18 months. An 18-month follow-up study showed that those in the partial hospitalization treatment group not only maintained their gains but also experienced statistically significant continued improvement in the areas of symptom distress, major clinical problems, hospitalization rates, and self-harm behaviors. A follow-up 5 years later reinforced the finding that partial hospitalization using MBT is clinically and statistically superior to treatment as usual. In contrast to the TAU group, the MBT group yielded significant reduction in suicide attempts (74% TAU vs. 23% MBT), decrease in diagnostic status (87% TAU vs. 13% MBT), decrease in years of further treatment (3.6 TAU vs. 2 MBT) and medication (1.9 TAU vs. 0.02 MBT), improved vocational status (3.2 years employment MBT vs. 1.2 TAU), and improved global functioning (45% MBT were GAF > 60 vs. 10% TAU).

SPECIAL ISSUES FOR MULTIPLE PROVIDERS

When patients have a PD, they are frequently ill enough to seek care from many professionals over a lifetime. There can be complications of the overlap in care, both in the past and simultaneously. During intake and diagnostic interviews, it is helpful to ask patients what their experience has been with previous therapists and providers. It can give clues both to the diagnosis (i.e., if there is a pattern of splitting) and to their likely transference to any therapist. Understanding why they left therapy can also be useful. For example, if they left because they were symptomatically better but not really improved, that could be an indication to work on deeper issues if they are able to tolerate doing.

If you are dealing with another provider simultaneously, we recommend asking permission to speak with the other clinician. It is important to define roles and understand the overall goals of therapy. For example,

most psychiatrists understand that if the patient is in acute crisis (i.e., someone with BPD who is suicidal) and needs hospitalization, they should have knowledge of how to get the patient admitted to an inpatient unit, and therefore they might instruct the patient to call them in crisis. However, if the main focus of the therapy is the parasuicidal behaviors, it might be more appropriate for the patient to call the therapist before he or she acts on any thoughts. If the clinicians are in contact, even if only initially and occasionally, they can clarify these roles to the patient and possibly avoid splitting later on. It is also not uncommon for patients to report to one clinician how well they are doing but report an extensive list of complaints to the other. In addition to encouraging and helping the patient communicate with the other provider, it can be important to share information throughout the care of the patient.

PHARMACOLOGY OF PERSONALITY DISORDERS

The psychopharmacological treatment of PDs is more complicated and less research based than the treatment of Axis I disorders. In the treatment of Axis I disorders, such as major depressive disorder or schizophrenia, physicians target research-validated *DSM-IV* criteria of each disorder in order to achieve remission. Randomized controlled studies of each diagnosis dictate appropriate treatments, and the disappearance of the criteria herald cure. In PDs, the targeted symptoms and desired outcomes of treatment are murky.

As previously discussed, personality is divided into temperament and character. Temperament is defined as a set of traits that are thought to be biologically determined and include novelty seeking, harm avoidance, reward dependence, and persistence. Character is thought to be determined more by environmental factors such as upbringing, abuse, and life experiences. In addition, life experiences shape our biology and temperament, and our temperament can shape our environmental experiences. Thus, the system is interconnected. Research has focused on temperamental traits as targets for medication as well as symptom clusters we recognize as being related to Axis I diagnoses.

Historically clinicians felt that psychotherapy was the only treatment leading to change in Axis II disorders. However, emerging evidence describes psychotherapy-induced changes in the brain (Gabbard, 2000a). Therefore physicians hypothesize that both therapy and medication can lead to similar biological changes that cause differences in behavior and relatedness.

Currently the FDA has not approved any medication for the treatment of personality disorders. However, the American Psychiatric Association (2006) has incorporated medication treatment into their recommendations for treatment of BPD, which will be detailed later in this section. Very few studies exist, and they are predominantly open-label or case reports. Randomized controlled studies are rare.

This lack of research into the medication management of PDs persists for many reasons. The main difficulties with these studies are defining targeted symptoms for treatment, teasing out existing comorbidities, establishing patient compliance, and defining desired outcomes. The facets of each PD that should be amenable to medication are not obvious. BPD, for instance, has undergone dramatic changes in its diagnostic criteria over the course of the *DSM's* history. Thus, patients called BPD in older studies may not correlate to current BPD subjects. Further, two BPD patients may present with startlingly different psychopathology. Defining a cohort of BPD patients is complicated.

A further difficulty in interpreting the research available is the lack of studies on polypharmacy, considering that the use of multiple medications is typical. A single study of polypharmacy used a combination of olanzapine-fluoxetine in BPD patients. This study showed improvement in the combination group that equaled that of the olanzapine group but exceeded the fluoxetine group. It also showed less weight gain from the combination group than olanzapine alone, an important improvement, as olanzapine can cause excessive weight gain (Zanarini, Frankenburg, & Parachini, 2004).

The very selection of Axis II patients for a study can be confusing due to comorbidities with Axis I disorders. If a patient in the study improves, there may not be a way to tell if it is due to improvement in the personality disorder or improvement in the comorbid Axis I disorder. Moreover, the mere presence of a comorbid disorder may signal a different “strain” of the personality disorder, which may lead to a different treatment response than would be seen in the presence of the personality disorder alone. Other problems with research in personality disorders are restrictive exclusion criteria that eliminate the sickest populations of patients, large placebo responses in studies, and high dropout rates.

One of the differentiating factors of Axis II pathology is its ego-syntonic nature. Axis I disorders are termed ego-dystonic, meaning that patients recognize and are distressed by their pathology and wish to improve their symptoms. In contrast, most Axis II pathology exists outside the realm of awareness. Clinicians have difficulty

enlisting these patients in any treatment, as they feel that there is nothing to treat! Convincing these patients, then, to enter a research study would surely prove difficult. Much of the existing research focuses on borderline personality disorder patients due to the emergent and ongoing nature of their demand on mental health care. Common BPD symptoms—such as suicide attempts, self-mutilation, and homicidal behavior—lead to frequent exposure to physicians and more likely diagnosis.

Measurements of improvement are not obvious. Research studies use many physician- and self-reported ratings scales to define improvement. The larger question remains—what is the medication really affecting? Are medications improving subclinical symptoms of Axis I disorders, leading to improvements in Axis II pathology? Are medications actively altering temperament? In addition, most studies performed thus far have been 5-week to 6-month trials and shed no light on the therapeutic use of the drugs as maintenance medications. Whatever the answer, medications are considered adjunct treatment to therapy, and only modest improvements should be forecasted.

Pharmacologic Management of Cluster A Disorders

Cluster A PDs encompass the odd, eccentric disorders and include paranoid personality disorder, schizoid personality disorder, and schizotypal personality disorder. These disorders are thought to fall on a continuum with the psychotic disorders of Axis I, particularly schizotypal personality disorder, which is associated with the schizophrenia spectrum disorders, as discussed earlier. The existing medication research in this cluster focuses on schizotypal personality disorder.

Interpretation of the literature proves awkward, as early studies often grouped borderline and schizotypal personality disorders together due to the concurrence of psychotic symptoms. Due to its relation to schizophrenia, clinicians conceptualize schizotypal personality disorder as a derangement in dopaminergic neurotransmission. Therefore neuroleptics, which affect dopamine, are the preferred medication and provide the most research evidence for this disorder.

To review, there are two categories of neuroleptics or antipsychotics—the so-called typicals and atypicals. The typical antipsychotics are older medications that block dopamine neurotransmission and have been used in psychotic disorders for over 50 years. These medications begin to work in several days and help alleviate hallucinations, delusions, and micro-psychotic symp-

toms such as derealization, depersonalization, and transient hallucinations often seen in BPD. Unfortunately, typical antipsychotics are associated with tardive dyskinesia—an irreversible movement disorder that has increasing incidence in patients on typical antipsychotics over the course of treatment. Typicals also can cause neuroleptic malignant syndrome, an acute syndrome of temperature dysregulation, muscle breakdown, and delirium, which can be fatal. Extrapyramidal side effects, movement problems, and cognitive blunting are also seen on typical antipsychotics.

Much excitement surrounded the advent of atypical antipsychotics. These medications not only affect dopaminergic neurotransmission but also affect a wide variety of neurotransmitters, including serotonin, norepinephrine, and histamine. This expanded coverage explains the atypicals' effects on mood and impulsivity in addition to psychotic symptoms. Atypicals have less risk of extrapyramidal side effects, tardive dyskinesia, and cognitive blunting. However, atypicals can be associated with weight gain and an increased risk of metabolic syndrome, which includes increased abdominal girth, increased triglycerides, and diabetes.

Results of studies on schizotypal personality disorder support the use of typical and atypical antipsychotics to improve the psychotic elements of the disorder, such as ideas of reference, paranoid ideation, and odd beliefs. Several studies have shown a positive response to typical antipsychotics. A study of haloperidol showed improvement in psychotic symptoms in patients with schizotypal personality disorder, some of whom also had BPD (Soloff et al., 1986, cited in Triebwasser & Siever, 2007). An open-label study of olanzapine showed decreased depression and psychosis (Keshavan, Shad, Soloff, & Schooler, 2004). In a comparison of thiothixene versus haloperidol in BPD and schizotypal personality disorder patients, thiothixene was superior in derealization, anxiety, and depression (Serban & Siegel, 1984, cited in Triebwasser & Siever, 2007). A further study of thiothixene in schizotypal personality disorder and BPD patients supported improvements in psychosis, but not depression (Goldberg, 1986, cited in Triebwasser & Siever, 2007).

Studies with atypical antipsychotics also demonstrate favorable results for schizotypal personality disorder. In the only known randomized controlled study of schizotypal personality disorder, risperidone led to a 30% improvement in positive and negative psychotic symptoms (Koenigsberg et al., 2003).

No studies exist for the psychopharmacological treatment of paranoid personality disorder or schizoid

personality disorder. Use of typical and atypical antipsychotics is based on the postulated dopaminergic basis of their symptoms.

Pharmacologic Management of Cluster B Disorders

Cluster B is the dramatic, erratic cluster of personality disorders and includes narcissistic personality disorder, histrionic personality disorder, borderline personality disorder, and antisocial personality disorder. Borderline personality disorder, as alluded to before, has commanded the largest amount of attention and research due to the nature of these patients' often life-threatening behaviors. Every class of medication has been employed in an attempt to improve their outcomes.

Unlike the neatly analogous symptoms of schizotypal personality disorder to the Axis I schizophrenia spectrum disorders, the diagnosis of BPD involves symptoms mimicking mood disorders, psychotic disorders, and anxiety disorders, depending on the clinical picture of each patient at any given time. Further complicating the picture are the frequent comorbid disorders of BPD, including eating disorders, anxiety disorders, mood disorders, and substance abuse and dependence. Therefore, again we see that what we are treating and why patients are getting better is a bit of an unknown.

To simplify, clinicians classify the symptoms of BPD into clusters: affective instability, cognitive-perceptual symptoms, impulsive aggression, and interpersonal psychopathology (Soloff, 2000). Affective instability describes the frequent mood swings, labile affect, and intense reactions to interpersonal events that are likened to bipolar and depressive disorders. Cognitive-perceptual symptoms, as previously described, are seen as schizophrenia spectrum like, although they are often short in duration. In terms of aggression, two types are described—hot and cold. Hot aggression is reactive and impulsive and seems to respond like affective instability to medication. Cold aggression is calculated and non-emotional and has not responded to biological treatments. This concept applies more to antisocial personality disorder and will be mentioned shortly. Interpersonal psychopathology is not thought to be directly affected by medications, but more obliquely modified as a result of other symptom improvement. The selection of medications follows the delineation of symptoms by clusters.

Antidepressants are the most commonly used medications in BPD. Specifically, SSRIs are the most prescribed medication and aim to treat depression, impulsivity, sui-

cidal and parasuicidal behaviors, and anxiety (Soloff, 2005). SSRIs increase the amount of serotonin in the patient's brain by inhibiting its reuptake and breakdown in neurons. Several facts support the use of SSRIs in BPD. First, women with BPD and a history of childhood sexual abuse were found to have alterations in their serotonergic system (Rinne, Westenberg, den Boer, & van den Brink, 2000). Second, low levels of serotonin metabolites in the spinal fluid of deceased patients have been correlated to more violent or impulsive suicides. Thus the behaviors of and historical facts about BPD patients imply a serotonin derangement that would be helped by an SSRI. Early studies showing improvement in symptoms in BPD employed fluoxetine and sertraline (Soloff, 2005). Interestingly, failure of one SSRI does not predict failure of other SSRIs; therefore multiple SSRIs should be tried before another class of antidepressants is tried. Also, high doses over longer treatment courses result in more success. Anger appears to improve with fluoxetine independently of improvements in depression (Salzman et al., 1995). Improvements in impulsivity can occur as quickly as the first week, although full efficacy for depression and anxiety is expected during the fourth to sixth week of treatment. In addition, the improvement in impulsivity occurs independently of any improvements seen in the other symptoms. As the side effects of SSRIs—gastrointestinal upset, headache, anxiety, insomnia, sexual dysfunction—are relatively mild (although, at times, quite upsetting!), an SSRI appears to be the obvious first- and second-line choice for BPD with symptoms of depression, anxiety, anger, or impulsivity.

Very little research has been conducted on BPD and the serotonin-norepinephrine reuptake inhibitors, which include venlafaxine and duloxetine; only venlafaxine has had a trial demonstrating decreased depression and self-injury (Markovitz, 1995, cited in Blais, Smallwood, Groves, & Rivas-Vasquez, 2008). Both work by inhibiting the reuptake and breakdown of both serotonin and norepinephrine, resulting in an increase in their concentrations in the brain. No trials were found with duloxetine in BPD, although it is indicated for major depressive disorder and generalized anxiety disorder and could be used to treat these comorbid conditions.

Monoamine oxidase inhibitors (MAOI) are antidepressants that work by permanently inhibiting the enzyme monoamine oxidase, which breaks down serotonin and norepinephrine as well as other neurochemicals, such as tyramine. These medications are older and were found to be particularly helpful in atypical depression. The symptoms of atypical depression, in contrast to the neurovegetative symptoms of typical depression,

include increased eating, increased sleeping, leaden feelings, and sensitivity to criticism. (Typical depression manifests with anorexia and insomnia.) Not surprisingly, MAOIs have been shown to help BPD patients who have atypical depression. No effect of MAOIs is noted on BPD patients without atypical depression. Use of MAOIs in general has been limited due to very dangerous potential side effects. The inhibited metabolism of tyramine can lead to a “hypertensive crisis” causing patients to go to the ER with spiking blood pressures and risks of stroke or heart attack. Ingestion of foods containing tyramine, such as aged cheeses and wines, must be avoided. Interestingly, Emsam, a newer formulation of the MAOIs, is an old MAOI in a patch worn on the skin instead of a pill. At the starting dose, which is often powerful enough for treatment, these dietary restrictions are not necessary. Taking away the strict dietary rules of the old pills may allow Emsam to make the MAOI mechanism of action more accessible to patients, although no studies exist for treatment of BPD patients at this time.

Tricyclic antidepressants are not recommended for BPD patients due to their side effect potential and a negative trend in the literature. Tricyclic antidepressants inhibit the reuptake and metabolism of serotonin and norepinephrine, with each medication affecting these neurotransmitters differently. The use of these medications is hindered by side effects including drops in blood pressure and heart arrhythmias. In fact a 10-day supply of a tricyclic antidepressant taken in overdose can lead to death. Not the best medication to have in your possession if you have intermittent and impulsive suicidal thoughts! This huge risk might be palatable if these medications produced impressive results, but the studies are predominantly negative; one study of amitriptyline even demonstrates behavioral activation and worsening of BPD patients (Soloff et al., 1986, 1987, cited in Triebwasser & Siever, 2007). Thus this category of antidepressants is best avoided.

Cognitive-perceptual symptoms are treated with antipsychotics, both typical and atypical. Older studies of patients with BPD showed efficacy of typical antipsychotics for not only psychotic symptoms, but also mood symptoms. Chlorpromazine, haloperidol, loxapine, and thiothixene all have positive studies in BPD patients with psychotic symptoms (Triebwasser & Siever, 2007). Atypical antipsychotics are shown to help with psychotic symptoms as well as mood and aggression. Risperidone and olanzapine have the best evidence and have shown efficacy in studies lasting 6 months (Soloff, 2005). A recent study of aripiprazole has also demonstrated improvements in obsessive-compulsive

symptoms, insecurity in social contacts, depression, anxiety, aggressiveness/hostility, phobic anxiety, paranoid thinking, and psychoticism scales (Nickel et al., 2006). In addition, quetiapine has had some positive case reports of decreased self-injury (Hilgar, Barnas, & Kasper, 2003, cited in Markovitz, 2004). Increasing severity of the patient’s symptoms predicts more pronounced response to an antipsychotic.

Clozapine, the first atypical antipsychotic, has shown impressive results but is plagued by serious potential side effects. Clozapine was used in a study of BPD patients all of whom had comorbid psychotic disorders. Clozapine was found to decrease self-mutilation (Chengappa, Ebeling, Kang, Levine, & Parepally, 1999). Several dramatic case reports of miraculous recovery are cited. However, clozapine is associated with a rare but fatal drop in white blood cells and requires weekly blood draws for 6 months followed by every other week for the entire treatment course. Considering the non-compliant behaviors of BPD patients, usage of clozapine should be limited to severe cases.

Mood stabilizers can treat the affective instability and impulsive aggression of BPD patients. In fact, atypical antipsychotics are also mood stabilizers and are all indicated in the treatment of mood disorders in addition to psychotic disorders. Other mood stabilizers include the anticonvulsants and lithium. The anticonvulsants are all medications approved first for seizure disorders, but later found to help with bipolar disorder symptoms. The understanding of this usage is that the same neural pathways mediating seizures may mediate impulsive aggression and affective instability. Some clinicians compare the “rage attacks” of BPD patients to seizures, and some comment on the resemblance of the derealization/depersonalization/hallucinations of BPD to temporal lobe epilepsy. Despite these hypotheses, most BPD patients have normal EEGs.

Anticonvulsants investigated in the treatment of BPD include carbamazepine, divalproex, topiramate, and lamotrigine. The use of carbamazepine has shown mixed results—a positive result was obtained in patients with a history of behavioral dyscontrol (Gardner & Cowdry, 1986, 1988, cited in Soloff, 2005). Another study that did not select subjects specifically with behavioral dyscontrol did not produce convincing results (De La Fuente, 1994, cited in Soloff, 2005). This discrepancy emphasizes that some medications only work for patients with specific symptom clusters. Divalproex improved agitation, anxiety, irritability, and impulsive aggression in open-label trials (Wilcox, 1995; Stein, 1995, cited in Soloff, 2005). Another divalproex trial with significant findings used BPD patients with comorbid

bipolar 2 disorder. The medication improved irritability, anger, and relationship status, but conclusions are limited due to the comorbidity of all subjects (Frankenburg & Zanarini, 2002). Placebo-controlled trials of topiramate in BPD patients show significant decreases in anger scales (Nickel, 2004, 2005, cited in Triebwasser & Siever, 2007). Lamotrigine, as well, has some case reports of effectiveness and a study demonstrating significant changes in anger scales (Tritt, 2005, cited in Triebwasser & Siever, 2007). Despite scant evidence, it should still be considered for use due to its relatively mild side effect profile (not excluding the rare risk of a quite serious rash.)

Lithium's mechanism of action is not well understood although its interaction with several neural pathways is thought to be responsible for the dramatic improvements in affective instability witnessed since the early 1900s. Lithium has also been found to be helpful in impulsive aggression and is used in studies of jail inmates to decrease aggression or noncompliance, as discussed later. In BPD patients, one study comparing lithium and a tricyclic antidepressant led to results of patients improving more on lithium, according to their therapists (Links et al., 1990, cited in Soloff, 2005). However, patient self-reports did not report substantial improvement. An obvious problem with a self-report in a BPD patient is the preexisting difficulties with self-perception, which could color his or her answers. Again, concerns about overdose exist due to lithium's narrow range between therapeutic and toxic levels and, therefore, may limit its usefulness.

Although not a primary symptom cluster, BPD patients certainly exhibit sporadic and severe anxiety. Anxiolytics such as the benzodiazepines have been used to help treat acute attacks of anxiety. Studies of alprazolam led to such pronounced behavioral disinhibition that trials were terminated early (Gardner et al., 1985, cited in Soloff, 2005). Clonazepam, however, has been used with some improvements in anxiety, impulsivity, and violent outbursts in BPD (Soloff, 2005). Overall benzodiazepines are mainly used in the hospital, as clinicians are nervous to supply such an addictive medication to a BPD patient for home use. Buspirone, which is a non-addictive anxiolytic, seems a reasonable option as well, but no studies for treatment of BPD exist.

Several other agents are briefly discussed in the literature. The use of opioid antagonists is associated with decreased self-mutilation in autistic children. Based on this finding, opioid antagonists have been used for self-injurious behavior in BPD with some success. Furthermore, one study demonstrated less dissociation (a symptom of BPD) with naltrexone (Bohus et al., 1999).

Omega-3 fatty acids have been touted by many sources as helping mood disorders. One study of these supplements demonstrated improvements, but the improvements occurred for the active compound as well as the placebo groups (Zanarini, 2003, cited in Triebwasser & Siever, 2007). Still, the harmless nature of these supplements makes them an attractive adjunct.

Several studies document the use of medication in the treatment of antisocial personality disorder. Although these patients present less to emergency rooms in self-inflicted despair, overcrowded prison systems are an homage to the difficulties our society faces at the hands of these patients. The criminal activities of antisocial patients, who are unencumbered by social conscience, lead to high rates of violence and financial losses. Medication studies have focused on attempts to decrease the impulsive aggression of these patients. One study of inmates with aggression showed that phenytoin, an anticonvulsant, decreased their aggressive acts; however, a follow-up study differentiating between hot and cold aggression stressed that cold aggression was unchanged (Barratt, 1991, 1997, cited in Triebwasser & Siever, 2007). Another study demonstrated improvements in aggressive acts in patients on lithium (Sheard, 1971, cited in Triebwasser & Siever, 2007). A case report of decreased aggression and improved work functioning after treatment with risperidone adds an additional option for treatment (Hirose, 2001.) These studies demonstrate the difficulty defining subject populations, as the authors use inmates or aggressive inmates, who may or may not fulfill criteria for a diagnosis of antisocial personality disorder. Still, given the societal costs, research into treatment of this condition is critical and the generalization of study results in the face of a desperate need to decrease violence is understandable.

No studies on histrionic or narcissistic personality disorder exist in the literature.

Pharmacologic Management of Cluster C Disorders

Cluster C is the anxious, avoidant cluster of personality disorders and includes OCPD, dependent personality disorder, and AVPD. These disorders are postulated to be related biochemically to the Axis I anxiety disorders, although recent research into OCPD suggests it may not be as closely related to the Axis I obsessive-compulsive disorder as originally thought. Still, abnormal serotonin neurotransmission is strongly implicated in these disorders. In a placebo-controlled trial of an

MAOI in patients meeting criteria for social phobia, many of whom also met criteria for AVPD, two-thirds of patients no longer met criteria for AVPD at the end of the trial (Fahlen, 1995, cited in Triebwasser & Siever, 2007). This study illustrates some of the difficulties previously pointed out in personality disorder research. Discerning the boundary between social phobia and AVPD is difficult, and this trial includes patients diagnosed with both. The improvement in AVPD symptoms may be direct medication effect on temperament, or medication effect on the social phobia, which leads to an atmosphere of decreased anxiety and stress, terminating in a decreased expression of the traits of AVPD. Thus, the extrapolation of treatment of AVPD from this study must proceed cautiously.

No studies are available on obsessive-compulsive personality disorder or dependent personality disorder. Antidepressants affecting serotonin are favored to treat these disorders.

ECT AND PERSONALITY DISORDERS

Due to the chronic and difficult nature of personality disorders, clinicians may be desperate and feel electroconvulsive treatment (ECT) might offer some relief for patients. However, it is widely accepted that ECT should not be used for PDs as a primary treatment due to the difficulty defining progress as well as the contribution of psychological factors that are unlikely to change with ECT. Some studies have shown that patients with Axis I disorders and comorbid PDs have less improvement of their Axis I pathology with ECT than those without this comorbidity, although not all results support that hypothesis. Still, it appears that Axis II pathology may make ECT less likely to succeed in some outcome measures. Most concerning is the path of using ECT in the hopes of changing personality traits instead of modulating Axis I pathology. Excessive amounts of ECT would be likely in PDs as a result of minimal improvement, and side effects, such as memory loss, could develop.

CONCLUSIONS

Overall, the emerging research on medication management of personality disorders, which grows from the body of imaging and genetic studies, appears promising. Improvements in some of the targeted clusters of symptoms lead to better functioning and decreased negative behaviors. However, the question remains whether personality itself can be permanently altered

by medication. The treatment of PDs can presently be conceptualized through three recognized progressive levels of care. In medical practice, physicians describe primary, secondary, and tertiary prevention or care. Primary prevention describes all the treatments and suggestions that physicians make in order to prevent a person from developing a disease. Secondary prevention refers to physicians' additional care of patients with risk factors or early signs of disease, but no chronic symptoms. Lastly, tertiary care refers to the treatment of patients who have already succumbed to disease. Markovitz, (2004) suggests that personality disorders may, at least for now, have to be seen as requiring tertiary care. Their treatment should aim to preserve as much function and optimize as many abilities and relationships as possible. While this outlook may seem bleak, the current view has developed through our understanding of the complexity of these disorders and frustration at the chronicity of these patients' difficulties. Hopefully we can move toward a model of primary prevention as more is learned about the genetics, epidemiology, and neurophysiology of these disorders.

Tourette Syndrome: A Model of Integration

Elia Abi-Jaoude
David Kideckel
Robyn Stephens
Myriam Lafreniere-Roula
Judith Deutsch
Paul Sandor

Tourette syndrome (TS) is a neuropsychiatric disorder with childhood onset. The condition is characterized by semivoluntary movements and sounds. The tics themselves are not a significant problem for many people with TS, and in fact, in most children the tics largely resolve in early adulthood. TS patients often exhibit other symptoms, including obsessions, attention deficit, hyperactivity, emotional dyscontrol, learning difficulties, and neuropsychological deficits involving prefrontal function, that often contribute to morbidity more than tics. Although TS is highly hereditary, identifying specific genes that contribute to its manifestation has been difficult, and TS is now thought to be inherited in a complex polygenic manner. Structural and functional neuroimaging studies have implicated the cortico-striato-thalamo-cortical circuitry, with evidence of striatal hyperdopaminergic activity, while neurophysiological studies have suggested an inhibitory deficit affecting the motor system. Treatment of TS patients is often focused on comorbidities, including learning disabilities, where psychological testing can be invaluable. Education and reassurance are often a sufficient intervention for tics. Specific interventions for tics include behavioral ap-

proaches, namely, habit reversal training, as well as pharmacological treatment, mainly with dopamine antagonists and alpha-2 agonists, though benefits should be weighed against potential adverse effects. Thus, the evaluation and treatment of TS are best carried out through the use of a multidisciplinary approach in an integrated clinical setting.

INTRODUCTION

TS is a familial neurodevelopmental disorder with childhood onset that manifests with involuntary movements and sounds. The first case was reported by Itard (2006) and the first series of cases was published by George Gilles de la Tourette in 1865 (Gilles de la Tourette, 1885), which prompted his mentor Charcot to give the disorder its eponymous name. This complex disorder presents with a combination of involuntary behaviors in the context of otherwise normal neurological functioning. Although not considered a part of the core symptoms, a variety of psychiatric and psychological symptoms such as attention-deficit/hyperactivity

disorder, obsessive-compulsive disorder (OCD), anxiety, anger control problems, and learning disabilities are frequently associated with TS. The clinical impact of TS typically extends beyond the patient and symptoms may affect relationships with family members and influence the educational and work milieu. This is more often the case in the presence of one or more comorbid conditions. Ideally, a multidisciplinary approach is necessary in order to provide an appropriate assessment and intervention for more complex patients. Margaret Mahler's formulation of TS, written in 1949, is still accurate: "While we believe we are dealing with an underlying organic pathology of the central nervous system, this somatic nucleus is acted upon and activated by psychodynamic forces" (Mahler, 1949). The evidence that has accumulated since then supports this view, as we shall outlined in this chapter. Until recently, TS was considered a rare disorder; however, we now know that 1%–3% of an average high school population has TS, as recently demonstrated by Robertson (2003). It is therefore clear that physicians and psychologists encounter a significant number of patients with TS, although they often do not present with tics as the first or even the main complaint.

We aim to provide in this chapter an integrated multidisciplinary approach to assessment and management of this common neuropsychiatric disorder. Case vignettes will be presented to illustrate the didactic sections. In addition, we will review the research studies on the neurobiology of TS.

CLINICAL GUIDE OUTLINE

Assessment Procedures and Instruments

TS manifests with involuntary movements and sounds, which are in principle detectable in an office setting during interview and examination. One needs to be aware that patients have the ability to suppress tics to a variable extent, sometimes for a few minutes, but often for much longer. The examiner needs to employ peripheral vision, since patients commonly suppress tics until the examiner is not looking at them directly, for example, while the examiner is taking notes. Similarly, the examiner needs to be alert to signs of suggestibility; in other words, when asking about specific tics, one should note whether the patient exhibits the tic shortly after it was mentioned. It is useful to employ one of the tic severity rating instruments, for example, the Yale Global Tic Severity Scale (YGTSS; Leckman et al., 1989)

that can serve both as a semi-structured guide to the assessment of tics and provide a means of recording the severity. There are several other tic severity rating scales, but none is as widely used as the YGTSS. The advantages and shortcomings of the various scales have been reviewed by Walkup, Rosenberg, Brown, and Singer (1992).

Diagnostic Criteria

Following are the diagnostic criteria for TS, according to the fourth edition text revision of the *Diagnostic and Statistical Manual of Mental Disorders* (2000):

Both multiple motor and one or more vocal tics have been present at some time, although not necessarily concurrently. (A tic is a sudden, rapid, recurrent, nonrhythmic, stereotyped motor movement or vocalization.)

The tics occur many times a day (usually in bouts) nearly every day or intermittently throughout a period of more than 1 year, and during this period there was never a tic-free period of more than 3 consecutive months.

The onset is before age 18 years.

The disturbance is not due to the direct physiological effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington's disease or post-viral encephalitis).

Differential diagnosis for TS includes seizure disorder, dystonia, ataxia, and tardive dyskinesia.

Screening for Comorbid Disorders and Behaviors

Although many cases of TS do not come to medical attention, the ones that present in medical offices often struggle with additional behavioral problems. The data from the general practice setting is not available; however, Freeman, Fast, Burd, Kerbeshian, Robertson, and Sandor (2000) published observations regarding 3,500 cases in various specialty clinics across the globe. Approximately 60% of the sample met diagnostic criteria for ADHD and 30% met criteria for obsessive-compulsive disorder. Anger control problems were present in about one-third of the cases. Sleep problems and anxiety were a complicating factor in 25% of cases each. Clinical assessment must include screening for common behavioral disorders. In addition, learning disorders, fine and/or

gross motor coordination problems, and speech abnormalities are present with increased frequency and must therefore be included in the screening process. Expertise from several disciplines, including psychology, speech pathology, and occupational therapy, must complement a medical and psychiatric assessment if all the above potential problems are to be detected, diagnosed, and addressed with appropriate interventions.

Investigations

A typical presentation, which includes a typical gradual onset of simple motor tics usually around the face, head, and neck with phonic simple tics following some months or years later, requires no investigation. Sudden onset of severe, simple, and complex tics, especially if accompanied by a history of simultaneous onset of obsessive-compulsive symptoms starting in the prepubertal period raises the possibility of PANDAS. This is not an easy diagnosis to make. One needs to obtain evidence of documented streptococcal infection within a few weeks prior to onset of symptoms (i.e., a positive throat culture combined with an appropriate antibody profile based on serial antibody titers).

Medication-Related investigations

Baseline investigations that include liver enzyme profile, glucose, lipid profile, hematology, and EKG are recommended before pharmacological treatment commences. It is also necessary to monitor weight and height in order to detect early any departure from normal (or baseline) BMI.

Learning

When learning disabilities are suspected based on uneven performance in different subjects, psychoeducational or more comprehensive neuropsychological testing is required to determine the specific profile of strengths and weaknesses. Such information is invaluable in developing an individualized education plan and can be also very useful in the selection of an appropriate psychotherapeutic intervention.

Patient/Parent Information and Resources

Once the diagnosis has been made, educating patients about the nature of their disorder is the next and often the most important intervention. Advice offered in the

office is often condensed and overwhelming to patients and their families. Written materials provide them with an opportunity to read and absorb the information at their own pace. Reliable information can be found on the Web sites of the Tourette Syndrome Foundation of Canada (<http://www.tourette.ca>) and the U.S. Tourette Syndrome Association (<http://www.tsa-usa.org>) with regard to diagnosis, treatment, and research. The sites also provide assistance locating professionals in various communities who are willing to see TS patients. These Web sites also offer a wealth of advice on how to deal with the education system, workplace, and insurance in various jurisdictions.

Quality of Life

There have been only a few studies attempting to examine how TS patients cope. It appears that tics are perceived as diminishing the quality of life by only a minority of patients with “pure” TS. The presence of OCD, ADHD, and other behavioral or learning problems has a much greater impact on the quality of life than tics (Bawden, Stokes, Camfield, Camfield, & Salisbury, 1998; Stokes, Bawden, Camfield, Backman, & Dooley, 1991; Thibert, Day, & Sandor, 1995). Storch, Lack, Simons, Goodman, Murphy, and Geffken (2007) measured the functional impairment due to tics and non-tic causes separately in a group of patients with TS. About 70% of the patients were noted to have functional impairment due to non-tic causes. There was a moderate inverse relationship between quality of life and self-reported tic severity in this group of children (Price, Kidd, Cohen, Pauls, & Leckman, 1985; Storch, Merlo, et al., 2007).

NEUROBIOLOGY

The pathology of Tourette syndrome is not fully understood. It is generally believed to be a disorder of the basal ganglia, although there is also evidence for disruptions in cortical processing. Here we will review models of basal ganglia organization and discuss the possible neuroanatomical basis of tics.

Basal Ganglia Organization

The basal ganglia are a group of interconnected nuclei located at the base of the cerebral cortex. They are involved in the control and production of movement. These nuclei include the globus pallidus, caudate, putamen, subthalamic nucleus, substantia nigra, and

striatum. The interconnections among these structures are complex, and a number of models have been developed to describe how basal ganglia dysfunction may account for the symptoms of various movement disorders. The basal ganglia are also part of cortico-striato-thalamo-cortical (CSTC) loops, which are involved in not only the control of movement but also the processing of limbic information. The input to the basal ganglia from the cortex is through the striatum and subthalamic nucleus, and its output through the substantia nigra reticulata and internal globus pallidus (GPi). The substantia nigra reticulata and GPi project to the thalamus, which projects back to the cortex, thus completing the CSTC loop.

Models of basal ganglia organization have been developed to help us understand basal ganglia dysfunction in movement disorders (Gale, Amirnovin, Williams, Flaherty, & Eskandar, 2008; Utter & Basso, 2008). Briefly, three main models that have been proposed: (1) the rate model, (2) the center-surround model, and (3) the oscillations model. The rate model (Albin, Young, & Penney, 1989; DeLong, 1990) is based on the existence of two pathways between the cortex and the GPi (basal ganglia output). The direct pathway is a disinaptic pathway through the striatum, and the indirect pathway is a multisynaptic pathway through the striatum, external globus pallidus, and subthalamic nucleus. Striatal neurons involved in each pathway can be segregated on the basis of their neurotransmitter content and the dopamine receptor type that they express. According to the model, hypokinetic disorders such as Parkinson's disease result from overactivity of the GPi (i.e. higher firing rates in this nucleus), while hyperkinetic disorders result from reduced activity in the GPi. Normal voluntary movement would result from a fine balance of activity in both pathways, which would facilitate desired movement while inhibiting competing motor patterns. This model, however, fails to explain why ablation or silencing of the GPi alleviates both hyper- and hypokinetic symptoms (dyskinesia and parkinsonism, respectively).

The center-surround model (Mink, 1996) is based on differences in the anatomical organization of the direct and indirect pathways—that is, that each subthalamic nucleus neuron excites a large number of neurons in the GPi (divergent indirect pathway), while striatal neurons inhibit selected subsets of GPi neurons (focused direct pathway). According to the model, the role of the basal ganglia is to select a specific motor pattern while inhibiting others, and this is accomplished by a center-surround organization of the focused striatal inhibition.

Both the rate model and the center-surround model assume that information in the basal ganglia resides in the firing rates of various nuclei (rate coding). There is increasing evidence, however, for the role of temporal coding. This evidence comes from findings on synchronization of discharge within and across basal ganglia nuclei and from the presence of oscillatory activity. In what may be termed the oscillations model, oscillatory activity at specific frequencies is exaggerated or suppressed in various nuclei, and this accounts for various symptoms of movement disorders. For example, there is correlative evidence that beta-band oscillations (8–35 Hz) have an antikinetic effect and there is evidence that they are reduced following levodopa treatment in Parkinson's patients correlating with improvements in bradykinesia and rigidity (Kuhn, Kupsch, Schneider, & Brown, 2006).

Although each model is supported by evidence, no one model has been found to account for all experimental findings, and a current view is that it is likely that aspects of all three models combine to explain basal ganglia circuits. We will now examine how basal ganglia dysfunction may lead to tics.

Neuroanatomical Basis of Tics

Several areas of the basal ganglia have been implicated in TS by both imaging studies and inference from treatment that seems to be useful in alleviating symptoms. It seems from clinical data that dysfunction in both dopaminergic and serotonergic neurotransmission may be involved in TS. Indeed, dopamine antagonists suppress tics and selective serotonin reuptake inhibitors mitigate obsessive-compulsive behaviors, a frequent comorbidity in TS patients. Brain areas where serotonergic and dopaminergic pathways interact have therefore been proposed as prime candidates for dysfunction in TS (Albin & Mink, 2006). These interconnected regions consist of the striatum, substantia nigra, and prefrontal cortex. The striatum is of particular interest because it has also been implicated in TS from functional imaging studies and also because tics can also be observed in Huntington's disease, a disease with known striatal dysfunction. Imaging studies, both structural and functional, have also implicated other brain areas such as the caudate, thalamus, and related cortical regions.

Excessive dopamine would lead to the production of unwanted movements through its action on the striatum. Dopamine acts on a specific type of striatal neurons (medium spiny neurons—MSNs), and its action is either stimulatory or inhibitory, depending on whether the MSN expresses D1-type or D2-type

dopamine receptors. D1-expressing MSNs project to the GPi and substantia nigra reticulata (direct pathway), while D2-expressing MSNs project to the external globus pallidus (indirect pathway). Thus, dopamine action increases activity in the direct pathway and decreases activity in the indirect pathway. Since the direct pathway facilitates movement while the indirect pathway inhibits movement, this would lead to the expression of unwanted movements.

While excessive dopamine would cause aberrant striatal activity, this could also result from changes in the membrane properties of striatal neurons, which would alter their sensitivity to their inputs (Albin & Mink, 2006). According to the center-surround model, this would cause unwanted inhibition of the corresponding basal ganglia output neurons and disinhibition to the thalamocortical target, hence the release of an unwanted motor pattern. Another possibility is that, while normally entrained to synchronized oscillatory activity, clusters of MSNs associated with tics would become disengaged from this entrainment (Leckman, Vaccarino, Kalanithi, & Rothenberger, 2006). Normal oscillatory activity in the basal ganglia may play a role in the formation of habits as well as in the execution of voluntary actions. Abnormal oscillatory patterns could be correlated to the development of tics, which may be seen as aberrant habits.

TRANSCRANIAL MAGNETIC STIMULATION AS AN INVESTIGATIVE AND THERAPEUTIC TOOL

While deep brain stimulation requires the permanent implantation of electrodes in the brain, transcranial magnetic stimulation (TMS) is a non-invasive method of stimulating neurons. Although deep brain structures such as the basal ganglia are not accessible through the use of TMS, cortical neurons can be stimulated by an induced current generated by a coil placed over the skull. TMS can therefore address the presence of cortical dysfunction in TS. TMS can be used to probe specific neural pathways (single-pulse TMS), to examine relationships between cortical regions (paired pulse TMS), or as a treatment option (repetitive TMS, or rTMS). TMS studies to date have shown the presence of cortical hyperexcitability in TS patients (Gilbert, Sallee, Zhang, Lipps, & Wassermann, 2005; Heise et al., 2008; Orth, Munchau, & Rothwell, 2008; Orth & Rothwell, 2009; Ziemann, Paulus, & Rothenberger, 1997). Specifically, short interval intracortical inhibi-

tion and shortened cortical silent periods have been demonstrated. Regarding the use of rTMS as a therapeutic tool, improvement in tics following rTMS has been shown but is not specific to stimulation, as there was no major effect reported when rTMS was compared to sham stimulation (Chae et al., 2004; Munchau, Bloem, Thilo, Trimble, Rothwell, & Robertson, 2002; Mantovani, Leckman, Grantz, King, Sporn, & Lisanby, 2007; Mantovani, Lisanby, Pieraccini, Ulivelli, Castrogiovanni, & Rossi, 2006; Orth et al., 2005).

NEUROIMAGING

Although the precise neuropathology of TS has not yet been delineated, neuroimaging studies have linked this disease with both structural (Peterson et al., 2001; Singer et al., 1993) and functional (Fattapposta, Restuccia, Colonnese, Labruna, Garreffa, & Bianco, 2005; Peterson, Skudlarski, et al., 1998) abnormalities involving the basal ganglia, thalamus, and cerebral cortex. Current models of TS therefore implicate the pathways connecting subcortical and cortical areas—the CSTC circuit. CSTC circuits are multiple cortical-subcortical loops originating from and projecting back to the sensorimotor, orbitofrontal, association, and temporo-limbic cortices. Currently, it is unclear how the CSTC circuit regulates and initiates behavioral responses in the motor cortex. Medical treatment and their effects on TS have also substantiated the notion that striatal structures, rich in dopaminergic innervation, are a major substrate in the etiology of TS. Because typical treatment regimens include neuroleptics (e.g., haloperidol, risperidone), which are dopamine antagonists, several researchers have argued for a dopamine neurochemical hypothesis (Leckman & Cohen, 1999).

Structural Abnormalities

There is widespread agreement that structural and functional brain disturbances exist in TS. These brain regions include the basal ganglia, cortical regions, and the thalamus. The corpus callosum (CC) may also be involved. Singer et al. (1993) performed a volumetric magnetic resonance imaging (MRI) study of basal ganglia structures and lateral ventricles on 37 children with TS and 18 controls. Significant differences for measures of symmetry in the putamen and the lenticular region were observed. They also found that virtually all the controls (17 right- and 1 left-handed) had a left-sided predominance of the putamen, whereas in 13 of 37 TS subjects, a right predominance was found relative to

controls. In a comparison of TS patients with ADHD ($n = 18$) and without ADHD ($n = 19$), significant differences in the volume of the left globus pallidus and lenticular asymmetry were observed. These data indicate that in the TS + ADHD group, the volume of the left globus pallidus was significantly smaller than the volume of the right, and that lenticular asymmetry was due to a greater right-sided predominance in the TS + ADHD group. This study is important because it supports the notion that the basal ganglia are involved in the pathogenesis of TS and, according to the researchers, it also suggests that the comorbid problem of ADHD is related to changes that differ from those primarily associated with tics (Singer et al., 1993).

Ludolph, Juengling, Libal, Ludolph, Fegert, and Kassubek (2006) used voxel-based morphometry with MRI and compared 14 TS patients (with and without ADHD) to 15 healthy controls, all male. They found that TS patients exhibited gray matter volume increases in the ventral putamen bilaterally. One can reasonably assume that their TS patients were indeed pure TS, as ADHD was mild in their study sample and they used this variable as a covariate in statistical analyses. In a different study, Ludolph et al. (2008) found a significantly reduced proportion of amygdalar to total brain volume in TS males (mean age 12.6 yrs) compared to age-matched controls. However, the reduced amygdalar volumes correlated with ADHD symptoms as opposed to tic severity. The researchers noted, therefore, that it was unclear whether the reduction was due to TS or ADHD.

In one large-scale study, investigators compared children (age <18 years) and adults (age >18 years) on basal ganglia volumes (Peterson et al., 2003) and also found differences. In this study, Peterson et al. (2003) measured basal ganglia volumes with MRI in 127 young adults or children with TS (average age 18.7 years) and 130 healthy controls (average age 21 years). They found that caudate volumes were significantly smaller in children and adults with TS. They also found that lenticular nucleus (globus pallidus and putamen) volumes were smaller in adults with TS and in children with TS who were diagnosed with comorbid OCD. It is noteworthy that 33% of subjects in the TS group had a lifetime diagnosis of OCD, and 27% had a lifetime diagnosis of ADHD.

Thalamic abnormality has been implicated in the pathophysiology of TS as well. J. S. Lee, Yoo, Cho, Ock, Lim, and Panych (2006) used volumetric MRI to examine thalamic volume in TS boys. They assessed 18 boys with TS, ages 7–14 years, and 16 healthy controls and found that TS subjects had a significantly larger left

thalamus than did the controls. In contrast, no group differences were observed in the right thalamic volume; TS subjects also showed a significant reduction in rightward asymmetry in thalamic volume compared with the healthy subjects.

In a previous landmark study, Peterson et al. (2001) used MRI to compare 155 TS subjects and 131 healthy controls on measures of cortical volume (cross-sectional study design). The participants consisted of 177 (61.9%) children (age <18 years) and 109 (38.1%) adults (age >18 years). Sixty-two individuals in the TS cohort (40%) had a lifetime diagnosis of OCD, and 36 individuals (23%) had a lifetime diagnosis of combined-type ADHD. These researchers also stratified the groups by sex. In children with TS, they found that TS boys and TS girls had significantly larger dorsal prefrontal volumes than controls of the same sex. They also found that TS boys had smaller premotor volumes (the premotor region in this study included the supplementary motor area), larger parieto-occipital volumes, smaller orbitofrontal volumes, smaller subgenual volumes, and larger inferior occipital volumes. This finding is particularly interesting because the premotor, prefrontal, and subgenual regions are collectively involved with the planning and execution of normal behaviors, thought to be abnormal in TS. TS girls had larger parieto-occipital volumes and larger inferior occipital volumes than controls of the same age. Comparisons between normal and TS adults of the same sex indicated smaller dorsal prefrontal volumes in TS women, larger premotor volumes in TS men, larger parieto-occipital volumes in TS men, and smaller parieto-occipital volumes in TS women. Age-specific differences were such that dorsal prefrontal volumes in TS children were larger than those in controls, but by mid-adulthood (approximately 30 years of age), those volumes were smaller in TS than in control subjects. This inverse relationship also held true in the inferior occipital regions. Finally, these investigators also used the YGTSS to assess tic severity symptoms and found that the worst ever tic severity symptoms correlated inversely and most strongly with the orbitofrontal and parieto-occipital regions (bilaterally), such that increasing volumes were associated with fewer symptoms. They also noted that positive, albeit weaker, associations were seen between tic severity and volumes of the left sensorimotor and left midtemporal regions. The group also used a mixed-model analysis to investigate their data and found similar results when comparing 42 pure TS subjects with controls (i.e., no OCD or ADHD).

In summary, Peterson et al. (2001) showed that TS subjects (children and adults) have larger volumes

predominantly in dorsal prefrontal regions and parieto-occipital regions, and smaller inferior occipital volumes, than controls. When stratifying by age, they found that TS children had larger dorsal prefrontal and inferior occipital volumes than control children, but by mid-adulthood, the volumes were smaller in TS than in control subjects. The dorsal prefrontal volume differences were the most statistically significant.

More recently, a study conducted by Sowell et al. (2008) detected cortical thinning in the frontal and parietal lobes in TS children. Of note, certain measures of tic severity correlated with the degree of thinning in corresponding sensorimotor cortical areas.

Prognostic indicators of TS are useful not only to clinicians, but for brain function in general. Due to the waxing and waning nature of TS and its general decline with age, it would be fruitful to be able to predict the severity that TS individuals will exhibit in adulthood versus childhood. In fact, Bloch, Leckman, Zhu, and Peterson (2005) conducted a longitudinal study consisting of 43 children with TS in which clinical status and basal ganglia volumes were measured on MRI before age 14 (average age 11.4 years). Follow-up clinical assessments were conducted after age 16, an average of 7.5 years later. These investigators found that total volumes of the caudate (right + left) measured in childhood with the YGTSS correlated inversely with the severity of tics at the time of follow-up, such that smaller caudate volumes predicted worse tic severity. While these data do provide compelling evidence for neurologic predictors of TS in adulthood, the results may be confounded by the fact that 35% of this TS population also had OCD and 19% had ADHD. Interestingly however, total caudate volume also correlated inversely with the severity of OCD symptoms at follow-up, as per the CY-BOCS.

Further support for the finding that caudate volumes are inversely correlated with tic severity comes from a previous study by Hyde, Stacey, Coppola, Handel, Rickler, and Weinberger (1995), in which investigators performed morphometric analyses of MRIs of 10 monozygotic twin pairs discordant for severity of TS but concordant for the presence of tic disorders (mean age = 16.3 years). They found that right caudate volumes were slightly but significantly reduced in the more severely affected twins as a group compared with the less affected twin group (mean difference = 6%). Most of this difference was attributable to volume reduction in the anterior right caudate, which was smaller in the more severely affected twin in 9 of 10 twin sets. Furthermore, the mean volume of the left lateral ventricle was also found to be 16% smaller in the more severely affected twins than in the less severely affected twins.

Several studies measuring CC size in TS have either shown decreased total CC area (79% males; Peterson, Leckman, Duncan, et al., 1994), increased regional CC measurements (82% males in Baumgardner et al., 1996; 65% males in Moriarty, Varma, Stevens, Fish, M., Trimble, & Robertson, 1997), or no differences in CC area or its subregions (100% female; Mostofsky, Wendlandt, Cutting, Denckla, & Singer, 1999). More recently, a diffusion tensor imaging¹ study indicated that the CC in TS children (20 subjects, 100% male) showed less directional organization (lower fractional anisotropy values) than the CC in control children within five subregions of the CC (Plessen et al., 2006). Although this study included TS subjects with and without ADHD and/or OCD, similar results were obtained even when these comorbidities were controlled for.

In a more recent diffusion tensor imaging study, Kideckel, Lobaugh, McAndrews, Protzner, Mikulis, Gibson, et al. (in press) found no differences between pure and mild TS adults and healthy age-matched controls when comparing the CC, as well as the internal and external capsules.

Functional Abnormalities

Neural Correlates of Tic Suppression and Generation

Tics are thought to arise from anatomical and functional disturbances in the CSTC circuit. Peterson, Skudlarski, et al. (1998) were the first investigators to use functional MRI (fMRI) to study TS. This group studied 22 adults with TS, using fMRI during tic suppression. Subjects were compared during periods of voluntary tic suppression and spontaneous expression of tics. These investigators found changes in signal intensities in the basal ganglia, thalamus, and cortical regions. Specifically, they found that tic suppression was associated with increased signal intensities in the right frontal cortex and right caudate nucleus, and this in turn was associated with decreases in the subcortical activity of the globus pallidus, putamen, and thalamus. The magnitude of neuronal activity in the basal ganglia (including the right caudate nucleus) and thalamus was inversely correlated with tic severity.

In an event-related study by Bohlhalter et al. (2006), evidence was brought forward suggesting that paralimbic and sensory association areas are involved in the generation of tics. In this study, 10 TS patients were examined while spontaneously displaying a number of simple motor and vocal tics, including eye blinking, nose twitching, grimacing, abdominal tensing, wrist

and arm stretching, coughing, snoring, grunting, and barking. Brain activity was measured with fMRI at two time points: 2 s before tic onset (chosen to represent premonitory urge) and at tic onset. According to Bohlhalter et al., this time window was chosen due to the fact that neural activity associated with self-generated movements, most notably in medial premotor areas, precedes activation of primary motor areas by this interval, on average. Interestingly, these investigators observed that in the comparison of the aforementioned conditions, the most significant increased cortical activations occurred in the supplementary motor area (SMA) bilaterally, lateral premotor areas, and parietal operculum, bilaterally, prior to tic onset. Much less activation in these regions was observed at tic onset, whereas more activity was seen in the cerebellum and sensorimotor areas. Furthermore, exclusive activation was observed at tic onset in the superior parietal lobules, bilaterally, and the left dorsolateral prefrontal cortex. At tic onset, significant activations of the substantia nigra were also detected bilaterally, as well as scattered motor cortex activation, both of which were not present during the premonitory urge condition. Similarly, ventrolateral parts of the thalamus also showed significant activations 2 s prior to tic onset that were not present at tic onset. Additional activations prior to tic onset included paralimbic areas, including bilateral anterior cingulate cortex, insula (BA 13), and posterior putamen, bilaterally. These areas were less marked at tic onset. To summarize, Bohlhalter et al.'s results suggest that sensory association areas as well as paralimbic areas are important in the generation of tics.

Motor Function Is Abnormally Organized in Tourette Syndrome

Biswal et al. (1998) used fMRI to study activation in the sensorimotor cortex and SMA in TS patients. These investigators employed a bilateral finger-thumb exercise, which consisted of repeated, self-paced rapid rhythmic bilateral appositions of the thumb and first finger in response to a cue from the experimenter. Activated pixels in the sensorimotor cortex region and SMA were analyzed by the investigators. They found that the regions activated in TS patients and control subjects were similar; however, in the TS patients, the number and the dispersion of the activated pixels were greater, suggesting abnormal cerebral activation in TS.

In a different study, Serrien, Nirkko, Loher, Lovblad, Burgunder, and Wiesendanger (2002) also found abnor-

mal cortical activation patterns in TS with fMRI. Although the findings of this study are in the opposite direction to those of Biswal et al. (1998) in terms of cortical activation patterns, they nevertheless indicate an altered activation in the TS population compared to control subjects during motor movements. Importantly, Biswal et al. and Serrien et al. employed different behavioral paradigms. Briefly, Serrien et al.'s method had subjects grasping a plastic bottle filled with water between the thumb and the other fingers of each hand in an axial direction. The objects were held in a stable position and rested on the subjects' legs (baseline condition). During the motor tasks, the bottles were lifted vertically 10 cm and moved approximately 30° in the sagittal plane. In controls, these investigators' data revealed bilateral cortical activation patterns in the comparison of baseline and motor tasks: primary sensorimotor cortex (BA 4, 3, 2, 1), premotor cortex, SMA, and anterior cerebellum. In TS patients, however, only the primary sensory areas (bilateral sensorimotor cortex and anterior cerebellum) were significantly activated from baseline. Greatly reduced activation was also a feature of the TS group in the premotor cortex and SMA, as well as in the basal ganglia and thalamus. The researchers, however, did not specify which basal ganglia structures featured reduced activation. Serrien et al. suggested that the increased activation of secondary motor areas during baseline conditions observed in TS patients was due to the premonitory urge phenomenon.

Another study addressing voluntary movements with fMRI in one male TS patient found that he displayed a different activation pattern than the control subject. Fattapposta et al. (2005) described a 24-year-old man with childhood onset of involuntary movements and stuttering that became increasingly marked. This patient's neurological examination showed multiple motor and vocal tics, coprolalia, echolalia, and rituals. The patient was evaluated with neurophysiological tests, EEG, and MRI, all of which were normal. He was compared with an age-matched control subject on a motor task (blocked design) that consisted of a repetitive, bilateral tapping of the index finger ("usual") compared with the little finger ("unusual") in two separate block designs of 30 s, alternated with a 30 s rest period, a total of 5 times for each paired block. The TS patient was instructed to perform the movement as quickly as he could. Fattapposta et al. found activated voxels in the premotor cortex and SMA in both subjects. In the TS patient, no significant fMRI differences were observed: premotor cortex and SMA were activated during both the usual and unusual tasks. By contrast, the control

subject showed significantly increased premotor cortex and SMA activation during the unusual task, and premotor cortex activity was more evident than SMA activity during the usual task. These investigators suggested that the increased SMA activity during both movements in the TS patient “may reflect the use of more cerebral cortex to perform a voluntary motor task” (Fattapposta et al., 2005, p. 272).

In a recent study, Kideckel, Lobaugh, McAndrews, Protzner, Mikulis, and Sandor (in press) used fMRI to compare finger tapping in pure TS and age- and sex-matched health controls. These investigators observed that a number of brain regions in the CTSC circuit, including BA22, BA6, BA24, BA40, BA9, and the left cerebellum, were differentially recruited by TS patients during finger tapping. In a few regions, the TS patients only weakly distinguished between rest and tapping (e.g., BA6); in other regions they showed much stronger discrimination (e.g., BA9, left cerebellum); and in others, activity patterns were actually opposite to those shown by controls (e.g., BA40).

Positron Emission Tomography

To date, many authors have argued in support of the dopamine theory of TS. This theory relies on indirect evidence of the effects that dopaminergic agonists and antagonists have on symptomatic relief or exacerbation of tics in TS.

Positron emission tomography (PET), either of cerebral glucose metabolism using [^{18}F] fluorodeoxyglucose or of cerebral blood flow using [^{15}O] H_2O , is another imaging technique that has been used to investigate TS. PET can scan the brain on a higher anatomic level of resolution than MRI (Frey & Albin, 2006). Whereas fMRI can investigate task-specific activations, PET examines the brain at rest and can target specifically defined neurons. By correlating regional metabolic rates for glucose, PET can be used to characterize networks of regions that may be affected in a neuropsychiatric disease. PET can also be used to target disorganized transsynaptic activity in patient populations (Clark, Kessler, Buchsbaum, Margolin, & Holcomb, 1984; Horwitz, Duara, & Rapoport, 1984; Horwitz et al., 1991).

In the first of three studies, Braun et al. (1993) compared 16 drug-free patients with TS and 16 age- and sex-matched normal volunteers. They found that TS patients exhibited decreased metabolic rates in paralimbic and ventral prefrontal cortices, particularly in orbitofrontal, inferior insular, and parahippocampal regions and in subcortical regions, including the ventral striatum

(nucleus accumbens/ventromedial caudate) and the midbrain. They suggested that “an altered relationship between limbic-related regions of the cortex and striatum and cortical regions involved in the initiation of movement may play a role in the pathogenesis of this illness” (Braun et al., 1993, p. 277). In the next study, Braun and colleagues (1995) found that cognitive and behavioral features commonly associated with TS (e.g., obsessions and compulsions, impulsivity, coprolalia, self-injurious behavior, echophenomena, depression, and attentional and visuospatial dysfunction) were correlated with increases in metabolic activity in the frontal cortices. In the third study, Jeffries, Schooler, Schoenbach, Herscovitch, Chase, and Braun (2002) found significant connectivity differences in the ventral striatum in TS versus controls. They also found changes in other brain areas, most notably the primary motor areas, somatosensory association areas, and insula.

Lerner et al. (2007) used [^{15}O] H_2O PET and compared nine TS patients with nine matched control participants during tic release states (in TS) and rest states (in controls). During tic release in TS, they found robust activation of cerebellum, insula, thalamus, and putamen.

In a recent study, Wong et al. (2008) measured the density, affinity, and brain distribution of dopamine D_2 receptors, dopamine transporter binding potential, and amphetamine-induced dopamine release (DA_{rel}) in 14 adults with TS and 10 normal adult controls with PET. Their results corroborated earlier findings by Singer et al. (2002). Specifically, they found that DA_{rel} was increased in the ventral striatum among subjects with TS, which, according to the authors, indicates that DA_{rel} is the primary deficit in TS.

GENETICS

Any clinician who obtains a careful family history of TS patients in his or her practice will be forced to conclude that TS tends to cluster in certain families. There is strong evidence from several lines of research that genetic factors play an important role in the etiology of TS. Adoption studies have demonstrated that TS is not a learned behavior. This was confirmed more rigorously by twin studies. The high concordance for TS—specifically, 53% and 8% for monozygotic and dizygotic twin pairs, respectively, and even higher for the presence of tics in general, 77% and 23% for monozygotic and dizygotic twin pairs, respectively—underscored the remarkably strong genetic influence on the risk of developing TS (Price et al., 1985). There are several reports

that first-degree relatives of an individual with TS have 5- to 15-fold increased risk of developing TS compared to general population (Hebebrand et al., 1997; Leonard, Lenane, Swedo, Rettew, Gershon, & Rapoport, 1992; Tanner & Goldman, 1997). On the other hand, the fact that only 53% of monozygotic twins were fully concordant for TS indicates that nongenetic factors significantly affect the expression of TS (Hyde, Aaronson, Randolph, Rickler, & Weinberger, 1992). The appearance of TS in genetically predisposed individuals may be triggered or modulated by as yet unknown non-genetic factors. Segregation studies attempted to determine the nature of the inheritance pattern; however, the contradictory results of the existing studies highlight the complexity of the real phenomenon. Initially the evidence supported an autosomal dominant pattern of inheritance (Curtis, Robertson, & Gurling, 1992; Eapen, Pauls, & Robertson, 1993; Pauls & Leckman, 1986). Subsequent studies that employed more sophisticated diagnostic criteria and assessment methods were more consistent with more complex patterns of inheritance (Comings et al., 1996; Hasstedt, Leppert, Filloux, van de Wetering, & McMahon, 1995; Walkup, LaBuda, Singer, Brown, Riddle, & Hurko, 1996). Current consensus suggests polygenic inheritance—that is, the simultaneous presence of several genes with a small effect—lead to the predisposition to TS. This implies that the nature and severity of symptoms as well as their ultimate course may depend on which combination of susceptibility genes is involved.

Despite much effort, no TS-specific genes have been identified to date, though the work continues. Several genes have been reported in recent years to be putative susceptibility genes for TS but none were confirmed in replication studies (Brett et al., 1990; Brett, Robertson, Gurling, & Curtis, 1993; Comings, 1995a; Comings, Comings, Devor, & Cloninger, 1984; Devor, 1992; Devor, Dill-Devor, & Magee, 1998; Gelernter, Pauls, Leckman, Kidd, & Kurlan, 1994; Huang et al., 2002; Lam et al., 1996; Nothen, Hebebrand, et al., 1994; Paschou et al., 2004). A recent case-control study identified SLITRK1 var 321 as a possible susceptibility gene for TS (Abelson et al., 2005). Unfortunately, this observation could not be confirmed in subsequent studies (Miranda, Wigg, Feng, Sandor, & Barr, 2008; Scharf et al., 2008). In fact, it is more likely that the observed association was the result of increased prevalence of var321 among the Ashkenazi Jewish population and not a pathogenic mutation (Keen-Kim & Freimer, 2006; Scharf et al., 2008).

Other specific genes have been excluded, for example, D1 receptor (Gelernter et al., 1993; Thompson, Comings, Feder, George, & O'Dowd, 1998), D2 receptor

(Devor et al., 1990; Gelernter et al., 1990; Nothen, Hebebrand, et al., 1994), D3 receptor (Brett et al., 1993), D4 receptors, and D5 receptor (Barr, Wigg, Zovko, Sandor, & Tsui, 1996, 1997; Nothen, Cichon, et al., 1994). Similarly, there were negative studies involving the 5HT1 serotonin receptor and tryptophan oxygenase (Brett, Curtis, Robertson, & Gurling, 1995; Cavallini, Di Bella, Catalano, & Bellodi, 2000; Erdmann et al., 1995), the 5HT7 receptor (Gelernter, Rao, Pauls, Hamblin, Sibley, & Kidd, 1995), and COMT (Barr, Wigg, & Sandor, 1999; Cavallini et al., 2000).

With the advances in the field of molecular biology, whole genome scans have become possible as the costs have decreased while the speed of the procedures has increased many-fold. Pakstis et al. (1991) used 228 markers to exclude about 50% of the genome as a site of TS susceptibility gene(s), though no linkage was found. A few years later the Tourette Syndrome Association International Consortium for Genetics (1999) reported weak linkage to two sites at 4q and 8p; however, the same year Barr et al. (1999), using 386 microsatellite markers, found no evidence of linkage. A linkage study of a single large pedigree including 35 subjects with TS and 14 subjects with chronic multiple motor disorder suggested that unspecified genes on chromosomes 5, 10, and 13 may contribute to the expression of TS (Curtis et al., 2004). A detailed examination of chromosome 17 was consistent with a TS susceptibility locus on 17q25 (Paschou et al., 2004).

Thus, despite much effort and international cooperation, progress in understanding the genetics of TS has been slow, as it has been with many other complex behavioral disorders. This is likely due to multiple reasons, including the possible heterogeneity of TS, polygenic inheritance, and unknown environmental factors that may influence the expression of TS in susceptible individuals. Perhaps parsing TS into discreet and more coherent components may lead to further advances in this area (Alsobrook & Pauls, 2002; Robertson, Althoff, Hafez, & Pauls, 2008).

Genetic Counseling

How are the genetics of TS important to practitioners? Patients commonly ask what caused TS in the first place. Later on they ask what the risks of another child, a grandchild, or a nephew having TS are. Family studies can inform the clinician's answers to these questions. One specific area of concern arises from the fact that TS is a genetic disorder. Some parents may need help with feelings of guilt about passing on "the gene," and in certain families there may be a need to help parents stop

blaming each other. In both situations it may be helpful to explain that the disorder is considered polygenic and thus it is likely that each parent contributed certain vulnerability genes. With regard to concerns about the risk that a future child may have TS, one can base one's response on the results of the family studies, which suggest that a risk to a child varies depending on gender and who has TS in the family. Generally, two parents with a TS diagnosis confer a higher risk than one parent with TS, and the risk depends also on the gender of the future child, since the risk to a male child is about 4 times that of a female child. However, it is necessary to note that female children in TS families are at an increased risk of developing OCD. As a result, the combined risk of having TS or OCD is roughly equal for boys and girls. As noted above, the first-degree relatives of an individual with TS have 5- to 15-fold increase in risk of developing TS compared to the general population (Hebebrand et al., 1997; Leonard et al., 1992; Tanner & Goldman, 1997). Finally, patients need to know that the data from the long-term follow-up studies suggest that about 80% percent of patients experience a substantial reduction in the tics' frequency and intensity by the end of their teens.

PANDAS

The concept of pediatric autoimmune neuropsychiatric disorder associated with streptococcal (PANDAS) infections has been discussed in numerous reviews (Dale, 2005; Lombroso & Scahill, 2008; Moretti, Pasquini, Mandarelli, Tarsitani, & Biondi, 2008; Muller, 2007; Scahill et al., 2006; Singer & Loisel, 2003; Snider & Swedo, 2004; Swain, Scahill, Lombroso, King, & Leckman, 2007). Although the possibility of links between infections and symptoms of TS and OCD had been raised in the late 1800s, most of the attention devoted to this has been in the past 15 years. After noticing a significant rise in both streptococcal infections and children presenting with new onset tics, Kiessling and colleagues (1993, 1994) found a several-fold increase in anti-neuronal antibodies reacting with frozen human caudate head sections in children with obsessive-compulsive symptoms, TS, and other movement disorders.

Swedo and colleagues (1998) described a series of 50 clinical cases of PANDAS and proposed the following five diagnostic criteria based on their clinical observations: (1) presence of OCD and/or tic disorder (the patient must meet lifetime diagnostic criteria for OCD or tic disorder); (2) pediatric onset—(symptoms first evident between ages 3 and onset of puberty); (3) episodic

course of symptom severity (clinical course consists of abrupt onset psychiatric symptoms or dramatic symptom exacerbation); (4) association with GABHS (group A beta-hemolytic streptococcus) infection (lifetime pattern of symptom exacerbation must be temporally related to GABHS infection) and ; (5) association with neurological abnormalities (i.e., abnormal neurological exam, for example, choreiform movements during exacerbation).

The presumptive pathophysiology of PANDAS involves "molecular mimicry," whereby, in predisposed individuals, antibodies developed by the immune system in response to infection with GABHS cross-react with neurons in the basal ganglia, resulting in movement disorders, including symptoms of TS. However, there have been mixed results from studies of serum titers of anti-streptococcal antibodies (Swain et al., 2007). There have been some intriguing experiments in which tic-like movements developed in rats whose brains were infused with sera of TS patients having high autoantibody titers, though, here again, there have been some inconsistent results (Scahill et al., 2006).

Strong epidemiological evidence in support of PANDAS came from a case-control study that found an increased likelihood of prior streptococcal infection in children newly diagnosed with TS, tic disorder, or OCD (Mell, Davis, & Owens, 2005). The risk of TS was found to be 13.6 times higher in those with multiple GABHS infections in the preceding year. This was recently replicated by another group using a larger sample, although the associations were not as strong (odds ratio = 1.54; Leslie et al., 2008). Of note, the more recent study also found a positive association between prior streptococcal infection and diagnoses of ADHD and major depressive disorder. Thus, given the lack of negative controls, the specificity of these associations is brought into question.

Two interesting recent prospective studies by the TS Study Group yielded mixed results (Kurlan, Johnson, & Kaplan, 2008; Singer, Morris, Gause, Gillin, Crawford, & Zimmerman, 2008). In the prospective case-control study, patients meeting criteria for PANDAS were found to have a higher rate of symptom exacerbation periods, and although there was a temporal association between streptococcal infection and these, most exacerbation periods did not have such a temporal relationship (Kurlan et al., 2008). In the prospective cohort study, there was no correlation found between clinical exacerbation episodes and an array of immune markers in cases of PANDAS (Singer, Gause, Morris, & Lopez, 2008).

There have been a number of attempts to treat cases of PANDAS. In the first such study, 37 children meeting criteria for PANDAS were randomized to prophylactic

penicillin or placebo in an 8-month double-blind trial (DBT; Garvey et al., 1999). There was no difference between penicillin and placebo in obsessive-compulsive or tic symptoms, but this could have been related to the lack of the antibiotic prophylaxis on the occurrence of infections. In a later DBT, 23 children randomized to either penicillin or azithromycin prophylaxis had lower rates of streptococcal infection and neuropsychiatric exacerbation episodes compared to their baselines during the year prior to the study (Snider, Lougee, Slattery, Grant, & Swedo, 2005). An important limitation is the lack of a placebo arm in this study.

Other studies have attempted plasma exchange and intravenous immunoglobulins (IVIG) in cases of PANDAS. In the first DBT, 30 children with PANDAS were randomized to a single course of plasma exchange, IVIG, or sham IVIG (Perlmutter et al., 1999). Both plasma exchange and IVIG resulted in significant improvements in obsessive-compulsive and tic symptoms after 1 month, and these improvements were maintained at 1-year follow-up. A subsequent 14-week DBT involving 30 patients with tic disorders not meeting criteria for PANDAS found no improvement of tic severity with IVIG relative to placebo (Hoekstra, Minderaa, & Kallenberg, 2004).

In summary, PANDAS remains a controversial diagnosis at this time. Although it is possible that immune factors may play a role in a small proportion of cases of TS, there is limited evidence to support routine PANDAS-related investigations or treatment at this time. Unfortunately, a recent study has suggested that prophylactic antibiotics have been inappropriately used in the community in the treatment of cases falling short of the full PANDAS criteria (Gabbay et al., 2008). Until further research more clearly establishes this as a diagnostic entity and appropriate treatments, it would likely be prudent to refer suspected cases of PANDAS to specialty clinics.

NEUROPSYCHOLOGY

Motor and vocal tics are often visibly identifiable after a short encounter with a child with TS. In contrast, possible learning difficulties and underlying neuropsychological deficits are often masked by relatively unimpaired and often stronger verbal skills and average cognitive test scores. More obvious behavioral problems, such as ADHD and OCD, may obscure the presence of learning disabilities. TS has characteristics similar to ADHD and OCD, suggesting neurophysiology overlap and making clarification

difficult. For example, there are high levels of motor restlessness in both TS and ADHD, and compulsive behavior and repetitive or preservative thoughts in both TS and OCD. In clinical populations, studies report up to 50% of children and youths with TS have also met criteria for ADHD (Cohen, 1992), while 11%–80% of individuals with TS have been reported to show obsessive-compulsive features (Apter et al., 1993; Cohen & Leckman, 1994; Leckman, Walker, Goodman, Pauls, & Cohen, 1994; Spencer, Biederman, Harding, Wilens, Faraone, 1995). Approximately 30% of adults with TS meet criteria for a comorbid diagnosis of OCD. Despite normal IQ, a diagnosis of TS exponentially increases the child's level of risk for compromised academic achievement and potential school failure, as well as difficulties in social development and peer relationships. Those with broad average-range intelligence (Mahone, Koth, Cutting, Singer, & Denckla, 2001) represent a vulnerable group of children with TS, as they may experience the frustrations, anguish, and emotional distresses associated with underachievement, academic delays, and social consequences. Children with tics are at potential risk of obsessions, compulsions, distractibility, increased restlessness, problems with focus and concentration, learning disabilities, and neuropsychological deficits; therefore, assessment of their psychological, neuropsychological, and educational needs should be based on their unique presentation and symptomatology.

It is not uncommon for a child with TS to come to the attention of a school psychologist as a result of poor academic achievement or behavioral and peer-related problems. However, as a consequence of limited school budgets, the psychological or psychoeducational assessment for students is often limited to cognitive screening for the purpose of identifying significant intellectual deficits in the student body. This type of brief cognitive assessment often "skims over" any underlying processing deficits, attentional problems, and neuropsychological weaknesses. Consequently, reports describe only the level of intellectual functioning and any significant discrepancies in academic achievement. For students with TS who possesses average-range intelligence and manage to keep up with academic learning, their actual learning and neuropsychological deficits are easily missed, and thus an opportunity to improve their performance such as it better matches their true academic potential goes unrecognized. For students who continue to struggle with classroom achievement, the approach often involves channeling the child into behavioral programs that attempt to address the child's low productivity rate, attitude, and poor motivation.

However, this approach fails to address the underlying learning or neuropsychological deficits that are causing poor schoolwork production, and the child is not likely to progress academically at a greater rate than before the behavioral interventions, adding further to the frustration and discouragement of the student, parents, and teachers.

There is a general consensus among researchers and clinicians that children diagnosed with tics, or TS without comorbidity, do not possess higher rates of learning disabilities and neuropsychological impairment (Pennington & Ozonoff, 1996). However, variances in study results persist. Certain reports comparing neuropsychological abilities between children with pure TS and controls have identified deficits in visual processing, strategic planning, and executive functioning in tasks reliant upon fronto-striatal effort (Randolph, Hyde, Gold, Goldberg, & Weinberger, 1993). Indeed, it is not uncommon for children with TS and comorbid disorders such as ADHD and OCD to demonstrate mild to significant difficulties in one or more areas of cognitive function (Alsobrook & Pauls, 2002; Bornstein, Stefl, & Hammond, 1990; Freeman et al., 2000). The neurocognitive contributions of each comorbidity should be considered when in the assessment and evaluation of the individual with TS in an effort to capture the most comprehensive neuropsychological profile. This would be best achieved when the assessment is conducted by a professional who is aware of the potential neuropsychological and learning deficits associated with TS, ADHD, and OCD. The results of the assessment can be focused on the child's underlying abilities and strengths, with a clear understanding and interpretation of how the disorders affect and compromise the child's learning, memory, attention, concentration, written work production, and overall information-processing skills. Having comprehensive knowledge of the specific neuropsychological profile of the individual child allows schools, teachers, parents, and support staff to design a program or implement classroom modifications that enable the child to reach his or her full intellectual and academic potential.

Research exploring the specific learning disabilities associated with TS has yielded mixed results, in part due to variations in diagnostic criteria used to identify TS. In spite of this, it has been demonstrated that a significant number of children (26%–28%) in special education classes have identifiable tics, indicating a risk 5 times greater than that of their same-age peers without tics (Comings, 1995b; Kurlan, 1992). While executive functions are what tend to be impaired, it is clear that these arrays of cognitive deficits are not specific to the

diagnosis of TS alone and more likely are manifested due to both a biological predisposition and psychological causes. Given the wide spectrum of TS tic symptoms and severity in addition to the individual cognitive and learning impact of the commonly associated comorbid disorders, a “typical” neuropsychological profile in TS is difficult to ascertain.

Bearing these caveats in mind, the most frequently diagnosed learning difficulties in children with TS with comorbid disorders are weaknesses or deficits in executive functioning skills, cognitive processing speed, visuomotor skill integration, listening skills, reading comprehension, written expression, oral expression, mathematics calculation and mathematics reasoning, and memory. Memory deficits and weaknesses can include working memory (the amount of information that can be mentally manipulated at one time), procedural memory (memory of the sequence of activities required to successfully complete a task), and strategic memory (the ability to apply a previously learned strategy to a new situation). In contrast, strengths commonly emerge on tasks of declarative or explicit memory, that is, recalling abstract knowledge about the world, such as the names of all the professional athletes on a favorite sports team, and episodic memory, which is the ability to recall certain events that occurred or information about a particular place or time (such as specifically what one ate for lunch when visiting a local theme park 2 years earlier).

Executive functioning skills are considered the higher-order processes that enable us to successfully plan, sequence, initiate, and sustain our behavior toward a set goal, while concurrently incorporating feedback and making adjustments (cognitive flexibility) to the problem-solving strategies being applied along the way. Studies have hypothesized that the executive functioning of TS without comorbidity is restricted to impairment on a single task requiring inhibitory behavior, while in contrast, subjects with combined TS and ADHD represented the most significant level of performance deficits across several aspects of executive functioning, including poor performance on implicit memory (e.g., rating as true statements they have already heard, regardless of new information challenging the veracity of the memory), procedural (a form of implicit memory characterized by learning that is relatively slow and requires repetition over many trials, for example, riding a bike, tying shoes), weak multitasking skills and compromised inhibitory responses, compared to the comparison groups (Channon, 2006; Freeman et al., 2002; Georgiou, 1995; Pennington & Ozonoff, 1996.).

Cognitive processing speed refers to the amount of time required to visually observe or read a problem or

question, then mentally and cognitively interpret the information, perform the necessary mental problem-solving functioning procedure, and produce a written or oral response. In a recent small study, the cognitive processing speed of grammar and manipulated language objects without written or constructional output was found to be enhanced in children with TS compared to controls. It was proposed that the frontal/basal-ganglia abnormalities suggested in the TS population (Baxter, 1990; Hall, Costa, & Shields, 1991; Peterson, Skudlarski, et al., 1998) may not only be related to the expression of tics but also be correlated to other rapid behaviors, including the cognitive processing of rule-governed forms in language and other types of procedural language knowledge (Walenski, Mostofsky, & Ullman, 2007).

While language processing speeds in TS have recently been described as scoring within or above the range of probability, the addition of a motor component to time-sensitive tasks is commonly observed to produce below-average performances compared to other measured areas of cognitive skills in this same population. A number of studies have consistently reported weak or impaired levels of visuomotor integration in children with TS, which describes the neuropsychological function combining visual identification of the new information and response with the appropriate motor movement (such as copying from a classroom blackboard; Schultz et al., 1998). Slow visuomotor integration skills have been acknowledged in a large number of individuals with TS and are alternatively described in some studies as psychomotor problems, which are collectively reported as difficulty quickly executing a movement, such as in other basal ganglia-related motor disorder populations such as Huntington's disease. Taken together, individuals with TS represent a group at risk of presenting with relatively slow cognitive processing and combined psychomotor difficulties, which, when translated to classroom and academic performance, create a significant risk of poor performance, unfinished work, and underachievement. It may take an inordinate amount of time for these children to complete their tests and desk assignments, and they may have difficulties transferring visually observed material to their notebooks. It is not uncommon for parents and teachers to remark that the student with TS has difficulty "putting pen to paper" during creative writing tasks, mathematics activities, and testing scenarios. In contrast, when asked orally for the solutions, the student is frequently quite capable of providing correct and often elaborate and extensive responses. This discrepancy could discourage or frustrate child and teachers. Furthermore, such discrepancy may lead parents to develop perceptions that the student is

putting in a poor effort, has weak motivation and focus skills, and generally does not work to fulfill his or her potential. TS students may also experience interfering motor tics, attention and concentration confounds related to ADHD, and the perfectionist qualities of OCD, which may further compromise their writing and problem-solving speed abilities, overall cognitive processing speed, and written results. Evaluation and treatment by an occupational therapist can often be quite helpful in this regard. Where this is not a possibility or a satisfactory option, providing the child with TS access to voice-to-text software should be considered as an alternative to requiring handwritten assignments (e.g., essays, book reports); this enables the student to dictate his or her work directly into an electronic document format, which can then be printed, edited, and submitted. This option has been found in clinical settings to boost children's sense of accomplishment and self-esteem when they visually realize the volume of written text they are capable of producing, and the grades they can achieve on completed work assignments, without the frustration and often minimal results they previously experienced.

These factors, both independently and cumulatively, help in part to explain the unusually large discrepancies commonly reported in TS intellectual domains, where the subscales comprising the verbal intellectual quotient (such as vocabulary skills, verbal problem solving, oral expression) have been shown to be significantly stronger in up to 40% of individuals with TS (Coffey et al., 2000) than the nonverbal or performance intellectual quotient skill sets (including timed visuomotor tests, visuospatial, and visual perceptual tasks). With the recent introduction of more comprehensive neuropsychological testing, learning and functional deficits are easier to unmask. A significant level of discrepancy between stronger verbal and weaker nonverbal or timed motor-reliant cognitive skills has been described in 25%–55% of children with TS in studies and has consistently emerged at a prevalence well exceeding the normal population representation of 10% for significantly lower performance intellectual skills compared to verbal intellectual abilities (Bornstein, 1991; Chang, 2007; Izmeth, 1979; Shapiro, Shapiro, Young, & Feinberg, 1988).

In the child with ADHD or moderate attention problems in addition to TS, there are commonly academic weaknesses in areas dependent upon the expectations of an age-appropriate level of attention, focus, and comprehension, particularly on subjects requiring adherence and mindfulness of the material being presented. In terms of reading comprehension, cumulative math reasoning skills, and written expression (both in

creative writing and completion of math computation activities), attention skills can cause the child to lose focus, to forget the previous lines of material read, to have difficulty recalling the correct procedure to apply to a mathematics equation, and to find full sheets of questions overwhelming, resulting in not only poor task completion but weak recall of the information. What is known is that many children with TS have the ability to learn grade-appropriate material. However, this can often only be achieved once their processing deficits are understood and they are provided with a format of learning and task completion that enables them to effectively encode smaller “chunks” of material at one sitting, have the opportunity for rehearsal and repetition to ensure comprehension and understanding, and are allowed use of revised formats of expressive presentation (such as fill-in-the-blank and short answer vs. essay answers, and reduced number of items per page of assigned work to encourage completion) that promote adequate learning, retention, and expression of the new learning.

The neuropsychological profile of the child with TS remains undefined, and although the current trend in research is to define the common areas of cognitive weakness in the presence of an otherwise normal level of intelligence, identifying these unique learning difficulties in each individual and providing these children with appropriate educational supports remains an area deserving of more in-depth, comprehensive, well-designed studies. While most findings concur that neurocognitive impairment in TS is primarily associated with both comorbidity and the level of tic symptom severity, not the diagnosis of TS alone, visuomotor integration and inhibitory control deficits, which are highly associated with comorbid disorders, are frequently reported across many studies and thus constitute an area that should be regularly included in the neuropsychological or psychoeducational assessment of TS (Bloch, Sukhodolsky, Leckman, & Schultz, 2006b; Schultz et al., 1998).

In a comprehensive assessment of children and adolescents with TS, it is critical to acknowledge an emerging body of interesting research identifying the unusually high prevalence of sleep disorders, including restless leg syndrome, periodic leg movement disorder, and delayed sleep phase syndrome. While epidemiological studies estimate that sleep problems are present in approximately 10%–43% of healthy school-age children, a startling 25%–60% of patients with TS with comorbid ADHD complain of disturbed sleep (Barabas, Matthews, & Ferrari, 1984; Comings & Comings, 1990; Freeman et al., 2000; Glaze, Frost, & Jankovic,

1983; Jankovic, Glaze, & Frost, 1984; Mendelson, Caine, Goyer, Ebert, & Gillin, 1980; Nee, Caine, Polinsky, Eldridge, & Ebert, 1980). This awareness is critical to the treating clinician when daytime behavior and academic problems are identified, and a comprehensive polysomnographic sleep assessment should be considered. A formal polysomnographic study provides important information that assists in the accurate identification of potential sleep disorders that may be compromising the child’s daytime performance. Studies have shown that children with sleep disturbances commonly mirror symptoms of attention, concentration, and behavior problems, while conversely, proper treatment of sleep disorders can greatly reduce impulsivity, irritability, and concentration problems and improve school performance and overall temperament. The knowledge gained from the sleep study results may also assist in the differential diagnosis of comorbid disorders.

TREATMENT

TS is often mild and therefore no treatment is required. In general terms one needs to initiate treatment when the symptoms are distressing and/or when symptoms interfere with function. The tolerance for symptoms varies greatly among individuals, and much depends on the underlying personality, family attitude, and social context. Hence there can be no absolute rules about severity of symptoms that require treatment. This very personal decision is made by each patient/family, using the advice from the health professional after considering the specific factors in each situation at that given time. Since in the majority of patients TS symptoms improve substantially by the end of the teens, providing a clear diagnosis and information about etiology, prognosis, and treatment options is reassuring and may be the only intervention required.

In most patients with TS, the main difficulties arise not so much from the tics themselves but rather from comorbid conditions, namely OCD, ADHD, and learning difficulties. The treatments for OCD and ADHD are covered elsewhere in this book, but mention will be made here of specifics pertaining to comorbidity of these two conditions with TS. In fact, for many patients with TS, no specific treatment for tics is required beyond thorough psychoeducation and reassurance for patient and family, as well as linking to community resources for those interested. Active treatment of tics may be considered when these are impairing due to a number of different reasons. This may be related to the particular type of tics, as well as the number, frequency, intensity,

and complexity of the tics. Problematic tics may interfere with a person's ability to function; for example, frequent head-jerking or forceful blinking may interfere with a child's ability to read. Another potential consequence may be pain or tissue damage resulting from tics (accidental or self-inflicted), such as headaches or repetitive strain injury resulting from very frequent or intense head-jerking. In addition, certain tics can be socially impairing and this can occur in social settings that are not practically amenable to psychoeducation. When used judiciously, the different treatment options for tics can be quite beneficial to patients. In general, the least invasive of the treatments should be offered first where feasible and available, and more invasive interventions should be resorted to only when really necessary and after careful consideration of the potential risks and benefits. Another important consideration is the waxing and waning course of tics, which should be taken into account when one is trying to decide if a certain intervention was really helpful or if the improvement was just coincidental with the treatment.

Psychosocial and Behavioral Treatments

When parents receive a diagnosis of Tourette syndrome for their child, the response often ranges from relief (having an explanation for why their child has been displaying unusual and uncontrollable sounds and motor movements) to disbelief or denial (parents are sometimes oblivious of their child's tics and strive to explain or justify the behaviors within the normal spectrum of childhood) to anger or resentment, (looking to blame the genetic disposition of TS on one's spouse). There are also families who have exhausted multiple medical pathways prior to arriving at the diagnosis and come to the clinic overwhelmed with prior potential explanations, discouraged at the lack of benefit or improvements they have observed, and frustrated with the daily difficulties and challenges they have encountered with their child at school, socially, and in their own home and family relationships. Thus, providing good empirically based, comprehensive psychoeducation to families of children with TS is imperative, and a necessary component of treating the child with TS. This should be done with the intention of engaging the whole family and those outside the family who are involved with the child's well-being, and providing them with factual knowledge, including the natural course of TS (how tics can wax and wane over time, developmental expectations), and an understanding of the possible comorbid disorders, how the symptoms could be demonstrated in the child's daily life, and how important it is to adopt a

flexible approach to the child's needs. Importantly, the clinician can provide understanding, constructive strategies, and treatment solutions that endeavor to improve all spheres of the child's world, as well as balancing, improving, or sometimes repairing intra-family relationships (Azrin & Nunn, 1973; Bruun & Bruun, 1994; Dornbush & Pruitt, 1995; Peterson & Cohen, 1998; Roane, Piazza, Cercone, & Grados, 2002; Watson, Dufrene, Weaver, Butler, & Meeks, 2005; Woods, Watson, Wolfe, Twohig, & Friman, 2001; Woods & Himle, 2004; Woods, Twohig, Flessner, & Rolooff, 2003; Woods & Miltenberger, 1995). Indeed, psychoeducation is often all that is needed at the time for tic symptoms. Patients and families can be reassured that children usually outgrow their tics as they mature. Those around the patients should also be encouraged to ignore the tics, as a parent's repeated insistence that a child stop ticking can create a great deal of stress for the child. Furthermore, it can be helpful to provide psychoeducation to teachers and students in the school setting in order to increase awareness, understanding, and tolerance of tics.

The scope of this chapter prohibits a thorough review of the behavioral techniques demonstrated to be most effective for the treatment of OCD and ADHD, and these are covered elsewhere in this book. The body of literature is extensive, and many excellent books that provide detailed strategies and suggestions for non-pharmacological interventions are available for parents, teachers, teenagers, and children (Baer, 1992; Barkley, 2000; Chansky, 2000; Greenberger & Padesky, 1995; Halliwell, & Ratey, 1995; Jenike, 2004; Williams & Waite, 2009). For the child with TS and comorbidity, behavior modification strategies should be reviewed from the available literature for each disorder, and an intervention plan developed from the collective readings and available programs that most appropriately target the specific characteristics of the individual child (Kutscher, 2005).

Behavioral Treatments for Tics and TS

Since the early studies in TS, behavioral treatments have focused on the reduction or elimination of unwanted or interfering motor and vocal tics, while including a strong component of supportive psychoeducational therapy for both the child and family aimed at helping them understand the nature, course, and range of tics and tic-like behaviors. Pharmacological treatment of chronic and interfering tics has been shown to be effective for TS (Lavenstein, 2003; Sandor, 2003; Stephens, Bassel, & Sandor, 2004), although complete elimination of tics is not often achieved by pharmacological treatments, and unwanted side effects of the medications may outweigh

the benefits, prompting patients and families to look toward alternative or complementary interventions for tic reductions. The most consistently reported approaches include massed practice of tics, contingency management, relaxation training, hypnosis, and habit reversal.

Massed Practice

Massed practice refers to the frequent and intense performance of an unwanted tic over a restricted amount of time. This may involve practicing the target tic for a set time limit of 15 minutes with minimal rest periods (1–2 minutes) during the session, with the concentrated activity repeated a number of times each day. Approximately 50% of published studies report a reduction in tics following massed practice, although an equal number found no change in tic frequency or even an increase in tics (Peterson, 2007). There is also very weak evidence across all reported studies for maintenance of any tic reduction following discontinuation of the behavioral intervention, further reducing the current support for massed practice as an effective strategy for tic reduction in TS.

Contingency Management

A lesser-known behavioral strategy for tic reduction is contingency management, which involves making adjustments or modifications to the individual's environment to reduce or eliminate triggers for motor and vocal tics (such as avoiding situations that frequently result in increased tics) or the use of a tangible reinforcement for reduction of the tic frequency. One form of contingency management is the token economy system; however, recent research questions the use of token systems with very young children due to the risk of development of overreliance upon external versus intrinsic reinforcement for positive behaviors and actions. Most reports describe weak results with this type of functional-based treatment approach, perhaps due to the lack of control most children have over their tic expression and the general involuntary nature of tics, which renders the response-based strategies difficult to apply to reduction of tic expression. On the other hand, contingency management has been reported to be a successful nonpharmacological intervention for behavioral management with ADHD without TS (Kazdin, 1993) and is being studied more frequently in the rage and aggression management of children with TS and comorbidity. Although contingency management may not be a good choice for tic reduction, as part of good clinical practice, it is beneficial to identify with the child or adolescent and his or her family external situations or events that tend to provoke or elicit a significant

upsurge in tics, such as certain television shows and overstimulating activities (such as theme parks), and to work with the family to make alternative choices or to knowingly limit the child's exposure to tic-exacerbating situations when needed.

Relaxation Training

Relaxation training has been shown to be a therapy that has some, albeit modest, benefit for the treatment of tics, with reports of reduced and absence of tics during various relaxed states (Peterson & Azrin, 1992; Leckman et al., 1992). Studies have investigated various relaxation approaches, including progressive muscle relaxation, autogenic training, and behavioral relaxation postures, with equally modest results reported during the actual therapeutic sessions, and a consistent lack of maintenance of any tic reductions following cessation of the regular relaxation sessions (Bergin, Waranch, Brown, Carson, & Singer, 1998; Peterson & Arzin, 1992; Peterson & Cohen, 1998). It is common clinically, however, for parents to report a reduction in their children's tics following massage therapy, yoga, and other available relaxation therapies and interventions. Therefore, if is deemed that there is no risk of harm to the child, and he or she enjoys and wishes to continue the experience, then support should be given to families in exploring alternative relaxation options for their child.

Hypnosis

There is very little published evidence supporting the use of hypnosis, or self-directed imagery, for the successful application of tic reduction in TS. A few studies have reported multimodal therapy interventions that included hypnosis as a component, with findings of modest tic reduction during the therapeutic program (Kohen & Botts, 1987), although the specific contribution of the hypnosis therapy itself is unclear (Young & Montano, 1988). There remains a lack of literature specifically identifying effects of hypnosis on tics and TS independently of other coadministered therapies, and there have been no studies using well-defined control groups and clear screening for comorbidity. As such, hypnosis is not usually recommended as an effective treatment for TS at this time.

Habit Reversal Training

Habit reversal training is the most widely studied behavioral intervention for tic disorders and TS, with the highest level of consistently positive results for successful

reduction of both motor and vocal tics, both as an adjunctive therapy to improve the efficacy of medication and as an alternative treatment to pharmaceuticals for those unwilling or unable to tolerate medication (Azrin & Nunn, 1973; Bloch, 2008; Carr & Chong, 2005; Davies, Stern, Agrawal, & Robertson, 2006; Deckersbach, Rauch, Buhlmann, & Wilhelm, 2006; Deckersbach, Wilhelm, Keuthen, Baer, & Jenike, 2002; Dopfner & Rothenberger, 2007; Gilbert & Lipps, 2005; Gilman, Connor, & Haney, 2005; Grillo, Long, & Long, 2007; Himle, Woods, Piacentini, & Walkup, 2006; Mansdorf, 1986; Miltenberger & Fuqua, 1985; Miltenberger, Fuqua, & Woods, 1998; Peterson & Azrin, 1992; Piacentini & Chang, 2005; Verdellen, Keijsers, Cath, & Hoogduin, 2004; Watson et al., 2005; Wilhelm et al., 2003; Woods et al., 2003; Woods & Miltenberger, 1995; Woods, Miltenberger, & Lumley, 1996).

Of the five components comprising habit reversal intervention (awareness training, relaxation training, competing response training, contingency management, and generalization training), it is commonly the competitive response procedure that is most effectively applied in the TS population. Competitive response in therapy involves intentional isometric tensing of muscles in the opposite direction of the target tic for a brief period of time. A comprehensive description of suggested competitive responses is presented by Peterson (2007), with step-by-step procedures for parents to become proactive in identifying potential tics before they are clearly established, in order to avert development of new tics once those initially targeted have been reduced.

While it has been suggested that practice of behavioral therapy for tic suppression, such as habit reversal, places the individual at risk of experiencing an increase in tic severity and intensity, in the form of a rebound effect, following the cessation of the structured program or treatment (Comings & Comings, 1990), more recent studies have not reported evidence of this phenomenon, with the exception of temporary increases in single cases (Himle & Woods, 2005; Himle, Woods, Conelea, Bauer, & Rice, 2007; Himle et al., 2006; Woods & Himle, 2004). Overall, the consensus across existing studies provides adequate support for consideration of habit reversal training as an effective and practical option in the treatment of tics in TS, with more compelling empirical evidence due to be published soon with the completion of two ongoing large-scale, randomized controlled trials in the United States. In fact, initial findings from one such study, a 10-week NIMH-funded multi-site trial involving 126 children randomized to either behavioral treatment or psychoeducation and supportive therapy, have been quite promising (American Association of Child and Adolescent Psychiatry annual

meeting, 2008; 5th International Scientific Symposium on Tourette Syndrome, June 2009). The behavioral treatment, named Comprehensive Behavioral Intervention for Tics, entailed—in addition to habit reversal training as a core component—psychoeducation, addressing psychosocial elements associated with tics, and relaxation training.

Exposure With Response Prevention

A final mention is warranted for the behavioral modification technique called habituation, which has been increasingly reported as a strategy that can effectively decrease tic frequency and severity in TS individuals through exposure to premonitory sensations and response prevention of tics (Hoogduin, Verdellen, & Cath, 1997; Leckman, Walker, & Cohen, 1993; Peterson, Campise, & Azrin, 1994; Verdellen et al., 2004; Verdellen, Hoogduin, Kato, Keijsers, Cath, & Hoijtink, 2008). While direct comparison studies of exposure and response prevention and habit reversal have shown no significant differences in tic reduction (Verdellen et al., 2004), the goal of each therapy is unique. In a recent study of introducing exposure and response prevention in a structured series of therapy session, therapy was aimed at increasing the TS individual's personal awareness of the premonitory urges associated with his or her tics, and initiating suppression of the sensations or urges to tic for as long as possible. Positive results were reported following a series of weekly therapy sessions, as the sensory ratings associated with the premonitory urges (albeit subjectively measured) decreased significantly, and this reduction successfully generalized to situations of daily living outside the therapeutic environment (Verdellen et al., 2008). In comparison, while habit reversal emphasizes replacement of the unwanted tic with an opposing or competing activity or sensation, exposure and response prevention focuses on prevention strategies to reduce the emergence of tics by teaching the individual how to identify and suppress the premonitory urge experienced prior to a tic, until the sensation has diminished and the sensation to tic has passed. Although mainly small groups have been studied, based on the results published, exposure response therapy for individuals with fewer, less severe tics lends itself to consideration when one is exploring alternative therapies for treatment of tics in TS.

Social Risks and Interventions

While not all children and adolescents with TS have difficulties establishing and maintaining friendships,

there are many who struggle to have positive social experiences throughout their developmental years. The acceptance and understanding of tics among the classmates and peers of the child with TS is not always automatic, and unfortunately, as the child with tics reaches the mid-elementary school years, when tics tend to increase, and fellow students become increasingly aware of individual differences among themselves, there is a heightened risk of peer rejection, avoidance from other students, and increased emotional stress on the child with TS. A broad range of studies have described children with TS as less socially acceptable to their peers than other students; however, there remains uncertainty whether the negative social implications are directly related to the tics themselves, or whether problems with peer relations are equally a reflection of the child's negative self-perceptions and the additional behavioral risks associated with commonly comorbid psychiatric disorders, such as ADHD, OCD, anxiety disorders, learning disabilities, rages, and sleep disorders (Bawden et al., 1998; Carter et al., 2000; Himle et al., 2006; Miltenberger et al., 1998; Stokes et al., 1991; Woods et al., 2003; Woods & Marcks, 2005). Most commonly, children with TS and comorbid ADHD present with the highest prevalence of behavioral and social problems and tend to represent the highest risk group for poor social adaptation compared to those with TS alone (Bawden et al., 1998; Woods et al., 2008).

Providing educational services and educational materials to the child's school and classmates has been shown to help elevate or improve peers and teachers' acceptance of a child's tics, particularly when there is an emphasis on understanding the involuntary nature of tics, and the otherwise "normal" or positive attributes of the child with TS. In addition to focusing on the tics in TS, it is also important to clearly identify any comorbid psychiatric disorders and to address the specific symptomatology that may present in the classroom or in peer-related situations, in an effort to reduce the potentially negative impact of impulsivity, irritability, a short temper, hyperactivity, perfectionism, and compulsive or obsessive behaviors, which could be detrimental to the child's acceptance among and interactions with peers. Educational materials, including videos, as well as a wide range of resource literature and information designed for use by children, adolescents, parents, teachers, and health care professionals, are available through the Tourette's Association of Ontario (<http://www.tourettesyndromeassociation.ca>), the Tourette Syndrome Foundation of Canada (<http://www.tourette.ca>), and the Tourette Syndrome Association (<http://www.tsa-usa.org>). Another Web site that

is rich in resources is Life's a Twitch (<http://www.lifesatwitch.com>).

Many psychosocial therapies, including counseling and psychoeducation for families, have been shown to be positive alternative and adjunctive treatment interventions to psychopharmacology, with a focus on understanding the condition, improving the child's self-esteem and social functioning, and reducing interfering tics or maladaptive behaviors; however, there remains a paucity of studies demonstrating objective data to support direct improvement in peer acceptance following peer education programs (Friedrich, Morgan, & Devine, 1996; Marcks, Berlin, Woods, & Davies, 2007; Packer, 1997). Engagement of the parents, siblings, extended family, teachers, and support workers in the educational process, as well as fostering support and understanding for ongoing therapies, is essential and offers the best likelihood of a positive, accepting environment for the child across multiple spheres. The family who has the benefit of working with a multidisciplinary team will be well prepared to work with their child across all aspects of their daily functioning, with an enriched experience gained from each professional and the opportunity to develop an extensive understanding of the complexities entailing a diagnosis of TS.

Psychoanalytical Intervention

It may appear anachronistic to include a comment on psychoanalysis, in that the psychoanalytic framework is generally sidelined and imbued with misunderstandings, due in part to tendencies by psychoanalysts themselves toward *pars pro toto* errors. In consideration of complicated symptoms like tics, one-to-one correspondences between a symptom and its significance (e.g., as symbol of a specific unconscious meaning) is inconsistent with the body of psychoanalytic findings. Psychoanalysis offers a range of viewpoints for understanding any particular behavior and is not in itself incompatible with findings from other fields such as neurobiology. Among these psychoanalytic points of view is consideration of developmental phase, including the cognitive distortions typical of early childhood (e.g., egocentrism, confusion about the body), conflict and/or deficit, conscious and unconscious functioning, and adaptation. It should be noted that psychoanalytic hypotheses about unconscious content and the process of change are verifiable by objective criteria (Mahler, 1949; Weiss, 1986, 1990).

It is instructive to start with relatively uncomplicated case examples in order to clarify the usefulness of a psychoanalytic frame for clarifying some manifestations

of tics and for their treatment. A boy of 6 years developed a severe eye tic at the end of a summer just before the beginning of the school term. His eyes darted to the side and upward, contorting his face in a grimace. As he was quite a visually astute child who noticed details, as evidenced by his exceptionally accurate drawings, this writer brought up with him in a general way his ability to use his eyes to look at and notice things. In our brief exploration of looking and noticing, he told me that his father had told him not to look at the sun, as it could be very harmful to his eyes. He explained that he was curious about the sun and that he thought that he could look and not look at the same time, explaining that he could give a sidelong glance so that he did not have to turn his head in a direct and obvious way and still obey the prohibition. The next day the tic had disappeared.

For this child, the tic expressed both the wish to look and the prohibition against looking. From a psychoanalytic viewpoint, this is the basic construction of a symptom: a compromise formation between at least two tendencies, such as wish and prohibition or wish and defense. It is likely that the wish was powerful enough to need an inhibition because it was unconsciously connected to more fearful content. However, there was no need to explore any further for the tic to disappear. From child observation and treatment, we also know of the organizing and regulating effect of verbalization, allowing thinking to intervene between impulse or feeling and action. What had been an automatic motor reaction was now linked with a verbalized wish and prohibition, and the child demonstrated how he could have control over his impulse to look. Another example from this same child further illustrates the helpful relation between verbalizing and control of motor expression. He later developed a seemingly involuntary humping of his shoulders and upper back. At one point he drew an animal with a humped back and explained that the animal adopted this posture when it was about to attack. Again, this child's movements expressed impulse and inhibition, this time a conflict around aggressive content. Verbalizing how the posture worked allowed for a delay between impulse and action, introduced a causal connection rather than an automatic response, and allowed for the possibility of greater control over these movements, giving him greater control over this movement.

A third example of a simple tic comes from a 4-year-old child. His eye tic involved frequent blinking. In exploring his history, his mother recounted a time when she herself cried much, as she had just had a miscarriage and a favorite pet had died. She also recalled that her son had several times asked her to turn off the

television, as he was disturbed by what he was seeing. She asked her son about his memories of the pet, and she was surprised that he so readily remembered the sad time when she cried so much. Again, talking about these feelings and linking them with his own impulse to cry led to remission of his blinking. Also, this mother became more aware that her son wanted to have control over what he saw.

It is possible that these tics resolved with verbalization because of several factors: the conflicts were phase appropriate and these children were not impaired in their overall psychological development; they had good tools of self-observation that were of use in understanding their tics; and lastly, the tics were understood soon after they appeared, before they became complicated with a range of anxieties, secondary gains, and interferences in a wide range of functioning.

Pharmacological Treatment

As discussed previously, receiving a clear diagnosis and an explanation about the etiology and prognosis of this condition is usually reassuring to patients and their families. Although there is increasing evidence that habit reversal is a safe and efficacious approach to reducing tic frequency and intensity in children and adults, it may not be adequately effective in all patients, and more importantly, in most areas there is presently a shortage or a complete lack of trained therapists capable of administering the treatment. The situation is similar with respect to collaborative treatment for inflexible children who are prone to rages. When psychosocial intervention or behavioral therapy does not seem to be sufficient or is not readily available, one has to consider pharmacological intervention. A cost-benefit analysis is necessary in order to decide when to introduce medications. The hoped-for benefits and potential adverse effects of each medication are well known and documented. Unfortunately, the potential consequences of not treating symptoms that have a significant impact on the functioning and quality of life of TS patients are often not fully appreciated. This is particularly important when one is treating children or adolescents who are in their formative years. The untreated symptoms may attract unwanted attention, teasing, ridicule, and even ostracism and undermine the self-image and self-confidence of the patient. Further complications may include impaired relationships not only with peers but also with teachers, parents, and siblings.

Only about 15% of the clinical TS population presents with uncomplicated TS, while over 50% of TS patients deal with comorbid ADHD and approximately

30% have comorbid OCD. In addition, sleep problems, anger control problems, and anxiety are present in about 25%, 30%, and 25% of clinic patients, respectively. Often, several of these require pharmacotherapy; hence multiple medications may be needed. Naturally, potential adverse effects, drug-drug interaction and detrimental effects on the TS symptoms must be considered when one is deciding which medications to use.

Numerous different psychopharmacological approaches have been used in TS, but the mainstay medication treatments of tics have been the dopamine antagonists, also known as antipsychotics, as well as the alpha-2 agonists. The evidence for these two classes of medications is reviewed here, with emphasis on double-blind and controlled trials. Other less commonly-used medications for tics are reviewed subsequently.

Dopamine Antagonists

The dopamine antagonists comprise a large class of medications that are highly variable with respect to their receptor-binding profiles. These medications are known as antipsychotics because of their common effect of decreasing hallucinations and delusions in psychotic disorders via their D_2 -antagonist effects. The high-potency antipsychotics, that is, those that bind relatively strongly to the postsynaptic D_2 receptor, have been found to be most effective in the treatment of tics.

The first case of use of a dopamine antagonist in TS was published in 1961 by Seignot, a French psychiatrist who had a dramatically successful result with a trial of haloperidol in a patient with very severe tics who had undergone numerous prior treatments, including a lobotomy (see Rickards, Hartley, & Robertson, 1997). This generated much interest in the use of haloperidol and other dopamine antagonists in TS. In an early DBT on four adolescent patients who had failed prior treatments, haloperidol reduced tic significantly in comparison to diazepam (Connell, Corbett, Horne, & Mathews, 1967). Another small double-blind controlled trial of nine patients with TS found that both haloperidol and pimozide significantly reduced tics compared to placebo, and improvements could be maintained up to 20 months later in most patients (Ross & Moldofsky, 1978). A subsequent placebo-controlled crossover DBT involving 20 young adult patients showed a significant improvement of tics with pimozide (Shapiro & Shapiro, 1984). A retrospective review (Singer, Gammon, & Quaskey, 1985) and a long-term uncontrolled study (Goetz, Tanner, & Klawans, 1984) identified fluphenazine as another high-potency antipsychotic effective against tics. In a small placebo-controlled crossover DBT involving

10 subjects, fluphenazine, trifluoperazine, and haloperidol were all equally efficacious (Borison, Ang, Chang, Dysken, Comaty, & Davis, 1982). In contrast, a small DBT of clozapine, a low-potency antipsychotic, failed to show any therapeutic benefit in TS subjects (Caine, Polinsky, Kartzinell, & Ebert, 1979). A placebo-controlled study involving 57 patients with TS showed both haloperidol and pimozide to be superior to placebo (Shapiro et al., 1989), with haloperidol being slightly more effective. However, a later placebo-controlled crossover DBT of 22 child and adolescent TS subjects surprisingly showed effectiveness of pimozide but not haloperidol, which was limited by side effects (Sallee, Nesbitt, Jackson, Sine, & Sethuraman, 1997). The lack of efficacy of haloperidol in this trial conflicts with previous trials involving haloperidol and with a large body of clinical experience supporting the efficacy of haloperidol in tic suppression.

As newer antipsychotics became available, there was interest in using these in TS in the hope of avoiding side effects known to occur with dopamine antagonists, especially dystonia, akathisia, and parkinsonism. A small controlled crossover trial involving only four subjects with severe TS favored olanzapine over pimozide (Onofrij, Paci, D'Andrea Matteo, & Toma, 2000), but this has yet to be replicated in a larger study. Otherwise, there have been only open-label studies with olanzapine since then (Budman, Gayer, Lesser, Shi, & Bruun, 2001; McCracken, Suddath, Chang, Thakur, & Piacentini, 2008; Stamenkovic et al., 2000; Stephens et al., 2004). Two 8-week controlled DBTs, one involving 48 subjects (Dion, Annable, Sandor, & Chouinard, 2002) and the other involving 34 subjects (Scahill, Leckman, Schultz, Katsoyich, & Peterson, 2003) with wide age ranges, demonstrated effectiveness of risperidone compared to placebo. Risperidone was also shown to be at least as effective as pimozide in a 12-week DBT of 50 adolescent and adult patients (Bruggeman et al., 2001), as well as an 8-week crossover DBT of 19 child and adolescent patients (Gilbert, Batterson, Sethuraman, & Sallee, 2004). A single-blind study also showed similar effectiveness of risperidone to clonidine (Gaffney, Perry, Lund, Bever-Stille, Arndt, & Kuperman, 2002). A 56-day placebo-controlled pilot DBT of ziprasidone in 28 child and adolescent patients showed effectiveness in treating tics (Sallee et al., 2000). Otherwise, only case reports have been published for quetiapine (Chan-Ob, Kuntawongse, & Boonyanaruthee, 2001; de Jonge, Cath, & van Balkom, 2007; Mukaddes & Abali, 2003) and the newer antipsychotic aripiprazole (Budman et al., 2008; Davies et al., 2006; Djebara, Worbe, Schupbach, & Hartmann, 2008; Kastrup, Schlotter, Plewnia, & Bartels, 2005; Seo,

Sung, Sea, & Bai, 2008; Yoo, Choi, Park, Wang, Hong, & Kim, 2007).

Other less commonly used dopamine antagonists have also been studied in TS. Metoclopramide is typically used as an antiemetic and gastrointestinal prokinetic (Albibi & McCallum, 1983). After initial open-label trials (Acosta & Castellanos, 2004), an 8-week randomized placebo-controlled DBT in 27 children and young adolescents, metoclopramide was shown to be effective in reducing tics (Nicolson, Craven-Thuss, Smith, McKinlay, & Castellanos, 2005). Tiapride, an antipsychotic not available in North America, was found to be superior to placebo in a 6-week trial involving 27 children (Eggers, Rothenberger, & Berghaus, 1988), replicating a similar earlier finding in TS patients in a DBT involving a mix of patients with various movement disorders (Chouza et al., 1982). Sulpiride is another antipsychotic not available in North America but widely used for treatment of TS in the United Kingdom and Europe. Its efficacy is supported only by a retrospective review (Robertson, Schnieden, & Lees, 1990). Tetrabenazine, a dopamine antagonist that also depletes presynaptic monoamines, has been the subject of an extensive recent review (Porta, Sassi, Cavallazzi, Fornari, Brambilla, & Servello, 2008). It was initially tried in TS some 35 years ago (Sweet, Bruun, Shapiro, & Shapiro, 1974), and has shown positive results in long-term follow-up studies (Jankovic & Beach, 1997; Jankovic, Glaze, & Frost, 1984; Jankovic & Orman, 1988) and retrospective chart reviews (Kenney, Hunter, Mejia, & Jankovic, 2007; Paleacu, Giladi, Moore, Stern, Honigman, & Badarny, 2004), but there has not been a report of a controlled study with tetrabenazine in TS to date.

Adverse Effects of Dopamine Antagonists

Dopamine receptor antagonists are associated with a number of different adverse effects, though much of the knowledge about these comes from their use in populations with psychotic disorders (Correll, 2008; Stroup, Kraus, & Marder, 2006). Of particular concern has been the group of neurological side effects known as extrapyramidal symptoms (EPS). These include akathisia, dystonic reactions, parkinsonism, and dyskinesia, which can occur as tardive dyskinesia, a result of long-term dopamine antagonism, which occasionally is not reversible. Further possible effects include cognitive dulling, depression, and anxiety. Tetrabenazine acts by depleting dopamine from the presynaptic vesicles; hence it can precipitate pronounced depression in vulnerable patients. It is also associated with EPS. All the above agents have been associated with neuroleptic malignant

syndrome, which is an uncommon but serious neurological side effect that can be fatal if untreated.

Another important group of potential adverse effects due to dopamine receptor antagonists are metabolic side effects, which include weight gain, diabetes, dyslipidemia, and potential vascular consequences if exposure is of long duration (month and years). It should be noted that tetrabenazine does not increase appetite, nor is it associated with metabolic abnormalities.

Changes in cardiac electrical conduction leading to prolongation of the QTc interval, with the risk of sudden cardiac death, is another concern, particularly for higher doses of pimozide and ziprasidone. A recent retrospective cohort study found a dose-related increased relative risk of sudden cardiac death among users of dopamine receptor antagonists (Ray, Chung, Murray, Hall, & Stein, 2009; Schneeweiss & Avorn, 2009). Other possible side effects, particularly for lower-potency antipsychotics, include sedation due to antihistaminic effects and hypotension caused by alpha-2 blockade, as well as peripheral anticholinergic effects such as dry mouth, blurry vision, and constipation.

In addition, dopamine receptor blockade in the hypothalamus can result in hyperprolactinemia, the consequences of which may include sexual dysfunction, amenorrhea, galactorrhea, and gynecomastia. High-potency antipsychotics, particularly risperidone and pimozide, are especially likely to cause hyperprolactinemia. Interestingly, in a double-blind placebo-controlled double crossover study involving 26 children and adolescents with TS, prolactin elevation was found to be associated with response to pimozide (Sallee, Dougherty, Sethuraman, & Vrindavanam, 1996). Subjects who developed EPS were also found to have elevated prolactin levels in both haloperidol and pimozide, though much more so with the latter.

There were numerous early claims favoring the newer dopamine antagonist drugs, the so-called atypical antipsychotics, in terms of tolerability and safety, among other things. However, an early systematic review and meta-analysis found that there was no advantage in tolerability when medication dose was taken into account (Geddes, Freemantle, Harrison, & Bebbington, 2000). Furthermore, a number of more recent well-designed non-industry-funded large-scale studies in primary psychosis populations have demonstrated a lack of advantage of the newer drugs over the older ones (Jones et al., 2006; Miller et al., 2008; Sikich et al., 2008). The evidence in TS population is sparse and equivocal.

The receptor-binding profiles of antipsychotics are highly varied, precluding attempts to group them based

on any single hypothesis. It is likely that anti-tic effects of antipsychotics are largely mediated via their blockade of striatal D₂ receptors (Singer & Wendlandt, 2001). These receptors are also what mediate EPS (Kapur, Zipursky, Jones, Remington, & Houle, 2000). This supports the findings that high-potency antipsychotics—that is, those with a high affinity to D₂ receptors, such as haloperidol, pimozide and risperidone—are effective in treatment of tics but also more likely to produce EPS. On the other hand, low-potency antipsychotics, that is, those that require higher doses to bind to D₂ receptors to a clinically adequate extent, bind to many other non-intended receptors, thus resulting in adverse effects. Even this general guide is an oversimplification, and one needs to consider the unique properties of each different dopamine antagonist and, most importantly, the effects in the particular patient at hand (Correll, 2008).

Alpha-2 Agonists

Clonidine is an antihypertensive medication that decreases noradrenergic transmission by stimulating presynaptic alpha-2 receptor. Early trials of clonidine in TS yielded mixed results (Borison et al., 1982; Goetz, Tanner, Wilson, Carroll, Como, & Shannon, 1987; Leckman, Detlor, Harcherik, Ort, Shaywitz, & Cohen, 1985). This included a 6-month placebo-controlled crossover DBT involving 30 patients, with a rigorous primary outcome measure based on evaluation of 1-minute video clips of subjects that yielded negative results (Goetz et al., 1987). Clonidine outperformed placebo in a 12-week DBT involving 47 subjects with a wide age range (Leckman, Hardin, Riddle, Stevenson, Ort, & Cohen, 1991), and it was found to be equivalent to risperidone in an 8-week DBT with 21 children and adolescents (Gaffney et al., 2002). Clonidine has also been shown to be effective at reducing tics in children with a chronic tic disorder and ADHD in a multicenter randomized 16-week DBT with 136 subjects by the TS Study Group (Kurlan et al., 2002). The transdermal clonidine patch was studied in a recent large DBT (Du et al., 2008), after it previously yielded negative results in a small pilot DBT (Gancher, Conant-Norville, & Angell, 1990). In the more recent study, 326 child and adolescent subjects with different tic disorders, around half of whom had TS, were administered active treatment with a weekly clonidine transdermal patch, while 111 were in the control group (Du et al., 2008). There was a statistically significant improvement in the active treatment group compared to the placebo group after 4 weeks, but the difference in final mean total YGTSS scores was quite small. Guanfacine, another alpha-2 agonist, showed

some benefit for tics in an 8-week placebo-controlled DBT of 44 youth with tic disorders and ADHD (Scahill et al., 2001). However, in a subsequent 4-week DBT designed to assess neuropsychiatric effects of guanfacine using a total sample of 24 children and adolescents with mild TS, there was no improvement in YGTSS scores over placebo (Cummings, Singer, Krieger, Miller, & Mahone, 2002).

In terms of side effects, alpha-2 agonists can cause sedation, which can be quite common and significant as the dose is increased. Other side effects may include headaches, dizziness, hypotension, dry mouth, constipation, irritability, mood lability, insomnia, and impotence (Goetz, 1992). Often such adverse effects occur within the first 2 weeks of treatment, or after a dose increase, and then abate. Considering this, doses should be increased gradually in order to avoid significant decreases in pulse rate and blood pressure. Of particular importance is the awareness of rebound in tics and increase in pulse rate and blood pressure, as well as anxiety, with abrupt withdrawal (Leckman, Ort, Caruso, Anderson, Riddle, & Cohen, 1986). Furthermore, concern has been raised about guanfacine inducing mania in vulnerable children (Horrigan & Jarrett, 1999) or hallucinations (Boreman & Arnold, 2003). Although true prevalence is not known, this appears to be a rather rare adverse effect.

Dopamine Agonists

Although TS is viewed as a hyperdopaminergic condition, a number of rationales have been given for the use of dopamine agonists in TS. One such trial, based loosely on findings from animal models, the experimental D1 dopamine receptor agonist SKF 38393 showed no benefit in a DBT of patients with different movement disorders, including two subjects with TS (Braun, Mouradian, Mohr, Fabbrini, & Chase, 1989). It has also been suggested that stimulating presynaptic autoregulatory dopamine receptors with dopamine agonists may decrease dopamine transmission and ameliorate tic symptoms, based initially on response to apomorphine in a study of two TS subjects (Feinberg & Carroll, 1979). Talipexole, a dopamine agonist with preferential affinity for presynaptic autoregulatory dopamine receptors, failed both in efficacy and in tolerability in a DBT of 13 adult male subjects with TS (Goetz, Stebbins, & Thelen, 1994). In two open trials, pergolide, a mixed D1/D2/D3 dopamine receptor agonist with higher affinity for presynaptic than postsynaptic D2 receptors, showed benefit in a retrospective chart review (Griesemer, 1997) and in an open-label study (Lipinski, Sallee, Jackson, &

Sethuraman, 1997). Subsequently it was studied in two DBTs. In the first controlled study, 24 children and adolescents with TS were randomized to either placebo or pergolide for 6 weeks, followed by a crossover after a 2-week placebo washout (Gilbert, Sethuraman, Sine, Peters, & Sallee, 2000). Although YGTSS scores clearly improved in the second arm of the study, this was not the case in the first arm of the study, and secondary outcome measures based on clinician assessment and parent ratings did not separate from placebo. In the subsequent larger placebo-controlled DBT involving 57 children and adolescents with TS, pergolide resulted in a modest decrease in YGTSS scores after 8 weeks, but here again, the secondary outcomes based on clinician assessments and parent ratings failed to separate from placebo (Gilbert, Dure, Sethuraman, Raab, Lane, & Sallee, 2003). Finally, a single dose of levodopa under single-blind conditions in 6 adults with TS resulted in improvement of tics (Black & Mink, 2000). This is intriguing, as it cannot be explained by presynaptic inhibition, and the investigators argue that previous positive findings with dopamine agonists may have all been through direct postsynaptic dopaminergic effects, possibly through effects on different aspects of the tic generation process than those pertaining to response to dopamine antagonists. Overall, there is little evidence for clinical use of dopamine agonists other than pergolide, and even there the evidence is limited. Importantly, although pergolide has been generally well tolerated in trials, there have been reports of serious adverse effects, including pleural, retroperitoneal, and pericardial fibrosis; cardiotoxicity; and vasospasm (Scahill et al., 2006). Non-ergot dopamine agonists such as pramipexole or ropinirole are safer; however, there is no data as to their efficacy in treatment of tics.

Botulinum Toxin

Botulinum toxin is a potent poison that causes muscle paralysis by interfering with the release of neurotransmitter acetylcholine from nerve terminals. Locally applied in minute amounts, it has been used in the treatment of dystonias, among other things. An early open study in 10 TS patients with disabling focal dystonic tics found botulinum toxin to be effective in all subjects (Jankovic, 1994). Interestingly, patients noted a marked decrease in premonitory urges. This was noted again in a case report of a boy with severe coprolalia who received botulinum toxin injection in the vocal cord with significant improvement in his coprolalia and marked reduction of premonitory urges associated with his vocal tics (Scott, Jankovic, & Donovan, 1996). A smaller

proportion of subjects with different motor and vocal tics had benefit from botulinum toxin in a large open study (Awaad, 1999). In two other open studies, most patients had improvement in tics, as well as premonitory urges (Kwak, Hanna, & Jankovic, 2000; Porta, Maggioni, Ottaviani, & Schindler, 2004). In the only controlled DBT to date, most of the 18 subjects who completed the study experienced significant reduction in the targeted tics as well as premonitory urges with botulinum toxin relative to placebo. Unfortunately patients did not feel that the treatment reduced their tics overall (Marras, Andrews, Sime, & Lang, 2001). In a recent case report, botulinum toxin in addition to antipsychotic treatment resulted in resolution of violent dystonic neck tics in a patient with TS (Aguirregomez, Pagonabarraga, az-Manera, Pascual-Sedano, Gironell, & Kulisevsky, 2008). Indeed, botulinum toxin may be more useful in significant focal dystonic tics. The main adverse effects include weakness of the injected muscle and decreased voice volume when the vocal cords are treated, as well as transient soreness at the injection site (Scahill et al., 2006).

GABA Agonists

Diazepam, a benzodiazepine, was not found to be helpful for tics in an early placebo-controlled DBT with four adolescents (Connell et al., 1967). Clonazepam, another benzodiazepine, was found to show some benefit in an open trial (Gonce & Barbeau, 1977) and two chart reviews (Truong, Bressman, Shale, & Fahn, 1988; Steingard, Goldberg, Lee, & DeMaso, 1994). One of the chart reviews involved children with a tic disorder and comorbid ADHD, with clonazepam used as an adjunctive treatment to clonidine (Steingard et al., 1994). An interesting study of 20 TS patients found that those with higher red blood cell-to-plasma choline ratios were more likely to respond to clonazepam than to haloperidol (Merikangas, MeriKopp, & Hanin, 1985), but this has yet to be replicated. Clonazepam has not been studied in a controlled DBT. Clinical experience suggests that in severe cases of TS it may augment the effects of neuroleptics on tics. Progabide, a GABA receptor agonist, showed some tic reduction in two TS patients during an open-label study (Mondrup, Dupont, & Braendgaard, 1985), but it has never been the subject of a DBT in TS. Baclofen, a GABA_B receptor agonist, showed benefits in a large open trial (Awaad, 1999), but it did not significantly decrease tics in a placebo-controlled crossover DBT trial of 9 youth with TS (Singer, Wendlandt, Krieger, & Giuliano, 2001). Overall, there is inadequate evidence for the use of GABA agonists to reduce tics in TS.

Nicotine

Initial positive reports of the use of nicotine gum as an adjunct to haloperidol under open label (Sanberg, Fogelson, Manderscheid, Parker, Norman, & McConville, 1988; Sanberg et al., 1989) and single-blind conditions (McConville et al., 1992) led to findings similar to those of studies using the nicotine patch (Silver & Sanberg, 1993; Shytle et al., 1996; Silver, Philipp, McConville, & Sanberg, 1996) as an adjunct to haloperidol or as monotherapy (Dursun, Reveley, Bird, & Stirton, 1994). Subsequently a 33-day placebo-controlled DBT studied the nicotine patch as an adjunct to haloperidol in 70 children with TS (Silver, Shytle, Philipp, Wilkinson, McConville, & Sanberg, 2001). The nicotine patch adjunct was better than placebo in clinician- and parent-rated global improvement, but not in YGTSS scores. Furthermore, a significant proportion of patients experienced side effects that included nausea (71%), vomiting (40%), and pruritus (57%). The high prevalence of side effects, as well as the equivocal benefit in tics, precludes clinical use of nicotine in TS.

Other

A number of other drugs have been explored in TS, but there is no good evidence from rigorous controlled DBTs to support their use. Cannabis has been reported to reduce tics, according to patient accounts (Muller-Vahl, Kolbe, Schneider, & Emrich, 1998), and in a single-case trials (Muller-Vahl, Schneider, & Emrich, 2002; Muller-Vahl et al., 1999), which led to two small placebo-controlled DBTs with interesting results (Muller-Vahl, Schneider, Koblenz, et al., 2002; Muller-Vahl et al., 2003), although not nearly as impressive as what is described in patient accounts. While the difference in effect size may be inherent to the difference in study type, another consideration is that nabilone, the cannabinoid used in the controlled studies, may be less effective than marijuana. Studies with opioid agonists and antagonists have shown mixed results (Kurlan, Majumdar, Deeley, Mudholkar, Plumb, & Como, 1991; van Wattum, Chappell, Zelterman, Scahill, & Leckman, 2000; Chappell, 1994; Chappell, Leckman, Scahill, Hardin, Anderson, & Cohen, 1993). Interestingly, acute naloxone infusion decreased tics at low dose but significantly increased tics at the higher dose (van Wattum et al., 2000). The anticonvulsant levetiracetam showed positive results in an open-label study (Awaad, Michon, & Minarik, 2005) and in an extension entailing 4 years of monotherapy in 70 TS children and adolescents (Awaad, Michon, & Minarik, 2007). However, levetiracetam showed no im-

provement on any measure, in contrast to clonidine, in a recent small 15-week DBT with cross-over design (Hedderick, Morris, & Singer, 2009). Topiramate, another anticonvulsant, showed effectiveness in a chart review of 39 cases (Nelson, Bost, & Lesser, 2007). A more recent manufacturer-sponsored small DBT showed topiramate to be effective compared to placebo (Jankovic, Jimenez-Shahed, & Brown, 2009). Donepezil has shown positive effects in two case reports (Hoopes, 1999; Niederhofer, 2006) and in an open trial (Cubo et al., 2008), but it has not subjected to a controlled study. The antiandrogen flutamide showed inconsistent results in a case series (Peterson, Leckman, Scahill, et al., 1994) and a DBT (Peterson, Zhang, Anderson, & Leckman, 1998). There are reports that some calcium channel antagonists may reduce tics in TS patients (Micheli et al., 1990; Walsh, Lavenstein, Licamele, Bronheim, & O'Leary, 1986), but there have not been any DBTs to subject these to rigorous study.

Comorbidities

Given the high comorbidity between ADHD and TS, children with TS are often exposed to stimulant medications. The issue of stimulant medication potentially increasing or even resulting in new-onset tics has received much attention in the literature. Despite earlier concerns that stimulants cause or exacerbate tics (Borcherding, Keyser, Rapoport, Elia, & Amass, 1990; Castellanos et al., 1997; Feinberg & Carroll, 1979; Handen, Feldman, Gosling, Breau, & McAuliffe, 1991; Lipkin, Goldstein, & Adelman, 1994; Sverd, Gadow, & Paolicelli, 1989), the extent of this relationship was brought into question by subsequent DBTs (Gadow, Nolan, Sprafkin, & Sverd, 1995; Gadow, Sverd, Nolan, Sprafkin, & Schneider, 2007; Gadow, Sverd, Sprafkin, & Nolan, 1995; Gadow, Sverd, Sprafkin, Nolan, & Ezor, 1995; Gadow, Sverd, Sprafkin, Nolan, & Grossman, 1999; Castellanos, 1999; Kurlan et al., 2002; Law & Schachar, 1999). In the largest of these, a 16-week multicenter DBT involving 136 children with ADHD and a chronic tic disorder (the majority of which were TS) were randomized to clonidine, the stimulant methylphenidate, a combination of these, or placebo (Kurlan et al., 2002). One of the secondary outcome findings was that the proportion of subjects reporting worsening of their tics was not higher in the methylphenidate group than in the placebo and other groups. Of note is the fact that tic severity was found to be improved in the methylphenidate group compared to the placebo group (Kurlan et al., 2002). Nevertheless, more individuals reported tics as a dose-limiting side effect of methylphenidate, and the pooled data may not

uncover a proportion of individuals whose tics do increase with methylphenidate. Moreover, as is suggested by the investigators, there may have been a selection bias against children who had previously experienced tic exacerbation on methylphenidate (Kurlan et al., 2002). Furthermore, the study does not address potential long-term or dose-related effects of methylphenidate on tics (Goldberg, 2002). Thus, although these findings have made it more likely for stimulants to be considered in the treatment of ADHD comorbid with TS, one should still consider that methylphenidate may exacerbate tics in certain patients (Erenberg, 2005; Poncin, Sukhodolsky, McGuire, & Scahill, 2007).

OCD is another condition that is highly comorbid with TS. Furthermore, it has been suggested that OCD in the presence of a tic disorder represents a distinct category of OCD (Leckman, Rauch, & Mataix-Cols, 2007). Indeed, it has been suggested that the presence of tics makes OCD less responsive to selective serotonin reuptake inhibitors (McDougle, Goodman, Leckman, Barr, Heninger, & Price, 1993; Shetti et al., 2005) and predicts poorer long-term outcomes in OCD (Leonard et al., 1993). An early DBT demonstrated that adding haloperidol decreases OCD symptoms in fluvoxamine-refractory patients with comorbid tics but not in those without tics (McDougle, Goodman, Leckman, Lee, Heninger, & Price, 1994). A later study showed low-dose risperidone to be effective as an adjunct in OCD patients refractory to SSRI monotherapy, but the presence of a tic disorder was not a moderating factor (McDougle, Epperson, Pelton, Wasylink, & Price, 2000). A systematic review and meta-analysis found that the presence of a comorbid tic disorder was associated with a beneficial response to dopamine antagonist augmentation to SSRI in the treatment of OCD (Bloch, Landeros-Weisenberger, Kelmendi, Coric, Bracken, & Leckman, 2006), but this was not the case in another meta-analysis (Skapinakis, Papatheodorou, & Mavreas, 2007). A secondary analysis of the landmark Pediatric OCD Treatment Study found that the SSRI sertraline did not separate from placebo in children with comorbid tic disorders, but there was no such effect in the arms receiving cognitive-behavioral therapy (March et al., 2007). Finally, although less of an issue compared to stimulants, one should be aware of the possibility that tic exacerbation may occur as a side effect of SSRIs (M.S. Lee, Lee, & Kim, 2008). Overall, while cognitive-behavioral therapy and SSRIs should still be considered as first-line treatments in the treatment of OCD comorbid with TS, it appears that the presence of TS can decrease the likelihood of response to SSRIs, and a proportion of patients refractory to these may respond to augmentation with haloperidol or risperidone.

Summary

In summary, when, after careful consideration, a decision is made to treat tics with pharmaceutical agents, the two main classes of drugs to consider are the dopamine antagonists and the alpha-2 agonists. The dopamine antagonists haloperidol, pimozide, and risperidone have larger effect sizes and more empirical support than other agents. Nevertheless, many groups recommend starting with an alpha-2 agonist, for example, clonidine, or guanfacine, for which we also have good empirical evidence of efficacy and a generally more favorable side effect profile (Swain et al., 2007). These medications need to be titrated judiciously, with ongoing regular monitoring of potential side effects. Currently available medications are palliative, not curative. Given the known natural course of tics in TS, that is, that tics usually improve toward the end of the teen years, it is prudent to gradually taper and discontinue the medication when tics have been mild or not present at all for a significant period of time (6–12 months).

Neurosurgical Procedures Previously Attempted for the Treatment of Tourette Syndrome

Prior to and concurrent with the development of previously discussed basal ganglia models a number of brain regions were the target of ablative surgery in an attempt to treat cases of otherwise intractable Tourette syndrome (Rauch, Baer, Cosgrove, & Jenike, 1995; Temel & Visser-Vandewalle, 2004). Although these invasive procedures have been few and far between (Temel and Visser-Vandewalle identified only 65 reported patients in the literature in their recent review), several brain areas have been targeted. Although many reports lack information that would enable precise determination of the location of the lesion, the general areas targeted include parts of the frontal lobe, the limbic system, the thalamus, the infrathalamic region, and the cerebellum. Most reports mention improvement of tics following the procedure but these assessments were usually unblinded and did not include a quantitative assessment of tic reduction. Moreover, serious side effects have been reported, such as changes in sexual behavior (Hassler & Dieckmann, 1970) or speech and swallowing dysfunction (Leckman, de Lotbiniere, Marek, Gracco, Scahill, & Cohen, 1993). Therefore, despite some level of success, it is generally agreed that ablative surgery should remain an experimental procedure reserved for the most

refractory cases. Moreover, in this and other movement disorders, deep brain stimulation has gradually replaced ablative surgery, as it allows the reversible silencing of brain structures through high-frequency stimulation.

Deep brain stimulation (DBS) involves stimulating specific brain regions using chronically implanted electrodes. It has been used successfully for the treatment of movement disorders such as Parkinson's disease and dystonia and is currently being investigated for a variety of conditions that include mood and cognitive disturbances. Its use in Tourette syndrome was recently explored in a number of case reports and small-sample studies (Ackermans, Temel, & Visser-Vandewalle, 2008; Neuner, Podoll, Janouschek, Michel, Sheldrick, & Schneider, 2008).

The mechanisms of action of DBS are complex and beyond the scope of this chapter, but they have been recently reviewed in detail by several authors (see, e.g., Liu, Postupna, Falkenberg, & Anderson, 2008; Hammond, Ammari, Bioulac, & Garcia, 2008; Israel & Bergman, 2008; Montgomery & Gale, 2008; McIntyre, Savasta, Walter, & Vitek, 2004). Despite many years of research, these mechanisms remain unclear. Since DBS gives rise to similar effects as lesioning, it was initially assumed that high-frequency stimulation inhibits target structures. While there is evidence that this is the case, there is also evidence that some neural elements are stimulated by high-frequency stimulation. Factors that account for the complexity of assessing the mechanisms of action of DBS include the complexity of the environment surrounding the electrode, which includes different types of neural elements, which can be affected differently by DBS (cell bodies, axons, fibers of passage).

Initial impetus for DBS in TS patients was motivated by the reported success of thalamotomies in these patients. Hence, the first target explored with DBS was the thalamus, based on the influential report of Hassler and Dieckmann (1970) describing thalamotomies in three TS patients. In their paper, Hassler and Dieckmann describe making 10s of lesions in both the right and left thalamus of each patient, with positive outcomes. The location they targeted is customarily quoted to justify the specific target within the thalamus chosen for DBS in other studies. That target includes regions of the centromedian nucleus, the substantia periventricularis, and the ventro-oralis internus. The first DBS in TS study by Vandewalle, van der Linden, Groenewegen, and Caemaert (1999) targeted the crosspoint of the centromedian nucleus, substantia periventricularis, and nucleus ventro-oralis internus. Several groups have published results based on thalamic stimulation (Visser-Vandewalle,

Temel, Colle, & van der Linden, 2003; Maciunas et al., 2007; Servello, Porta, Sassi, Brambilla, & Robertson, 2008; Bajwa et al., 2007). Across groups, this procedure has resulted in tic reduction of about 49% (Neuner et al., 2008), sometimes lasting several years.

The second most popular target has been the globus pallidus (GP). The rationale for targeting the GP is that DBS in this region is useful in reducing hyperkinetic symptoms in Parkinson's disease such as drug-induced dyskinesia and that, as such, it would be useful for mitigating tics, which can be seen as a hyperkinetic symptom. Several groups implanted the GP in addition to the thalamus (Ackermans et al., 2006; Diederich, Kallsteis, Stamenkovic, Pieri, & Alesch, 2005; Houeto et al., 2005; van der Linden, Colle, Vandewalle, Alessi, Rijckaert, & de Waele, 2002; Welter et al., 2008) and a few implanted the GP alone (Dehning, Mehrkens, Muller, & Botzel, 2008; Shahed, Poysky, Kenney, Simpson, & Jankovic, 2007). In cases where both the thalamus and the GP were targeted and results compared within patients, GP stimulation usually gave better results in terms of tic reduction than thalamic stimulation. Overall, GP stimulation led to a 76% tic reduction (Neuner, Podoll, Lenartz, Sturm, & Schneider, 2009). Although a smaller number of patients have been studied under GP stimulation, it is reported that a multicenter study to test the effectiveness of pallidal stimulation is underway in France (see Welter et al., 2008).

Finally, there are a few reports of DBS in the nucleus accumbens/anterior limb of the internal capsule region (Flaherty et al., 2005; Kuhn et al., 2007; Neuner et al., 2009). The rationale for targeting the nucleus accumbens is that OCD behaviors are a frequent comorbidity of TS, and DBS of the nucleus accumbens in OCD patients has been performed. In the few patients in whom nucleus accumbens stimulation was tried, there was a reduction in tics by about 43% (Neuner et al., 2008) and in one patient's self-injurious behavior stopped following stimulation, while it was significantly reduced in the other patients.

In conclusion, DBS for TS in all targets reported to date seems to yield a positive outcome. A shortcoming of the currently available data is that most of these studies to date have consisted of case reports and small-sample unblinded studies, although there are exceptions, such as a randomized double-blind trial involving 5 patients (Maciunas et al., 2007) and a series of 18 patients evaluated in on-off stimulator conditions as well as sham (Servello et al., 2008). There is insufficient information at this time to recommend one target over the others, and it has been suggested that a large multicenter study is required to answer

this question (Neuner et al., 2008). Although further research is clearly needed in this area and is warranted by the positive preliminary results, caution should be exercised in making DBS more widely available for TS patients. DBS for TS patients remains an experimental procedure at this time. As such, appropriate patient selection is important to maximize the possible benefits to subjects (Visser-Vandewalle, 2007). This is particularly important because TS is not a degenerative disease like Parkinson's disease, but a disease where the symptoms wax and wane. Furthermore only a minority of TS cases require medical intervention, and only a minority of those cases are refractory to non-invasive treatment. A group of experts convened by the Tourette Syndrome Association has published detailed recommendations regarding patient selection and assessment for DBS in TS (Mink et al., 2006). Among these recommendations is the suggestion to select only patients with stable severe disease for a number of years in adulthood who have failed conventional pharmacological treatment with appropriate doses and durations of three classes of medications, which should include an alpha-adrenergic agonist, two dopamine antagonists, and a benzodiazepine. Moreover, they suggest selecting patients who have previously tried behavioral therapy, which has been shown beneficial and is low risk. A last word of caution regarding DBS and TS regards the presence in some TS patients of self-mutilatory behavior. One group reported poor wound healing on the scalp because of a compulsion to touch it, and this resulted in the need to cast the patient's arms and chest to prevent touching until the wound was healed (Servello et al., 2008). Again, this highlights the importance of adopting a cautious approach in using DBS for TS because it is, at this time, still at the proof-of-principle stage as therapy for disorders of mood, behavior, and thought (Rabins et al., 2009).

INTEGRATED CLINICAL PRACTICE

Patients with TS have a wide range of presentation in terms of severity and comorbidity, among other characteristics. Uncomplicated cases of TS can often be managed by frontline care providers such as family practitioners, pediatricians, community psychiatrists, neurologists, and clinical psychologists. However, for more severe and/or complex cases, the potential treatments are highly varied and are best delivered in an individualized manner in the context of an integrated multidisciplinary clinic. Though not yet commonly the case, such clinics should

be staffed by mental health care providers who trained in the different psychological and behavioral treatments for TS, particularly habit reversal training. These could be carried out by psychologists, psychiatrists, or social workers. Neuropsychologists and psychometricians can regularly provide psychological assessments when needed. Social workers can be invaluable for dealing with parenting and other family issues, as well as advocating in patient schools and communities. Speech language pathologists can help with common phonological problems and stuttering, as well as social communication difficulties. Occupational therapists can provide help for subjects with sensory hypersensitivities, and such challenges as getting thoughts into writing, as well as fine motor difficulties, which may affect handwriting. Psychiatrists should be able to integrate the complex care these patients require and may treat tics or related difficulties with medication when required. Such clinics also benefit from readily available general practitioners, pediatricians, and neurologists to act as consultants for relevant physical problems. Finally, when it is impractical to have all these care providers in the same physical space, as is often the case in community settings, virtual integrated TS clinics can be a means to deliver the necessary care through open and ongoing communication and collaboration among practitioners from different fields with the training, experience, and availability to assess and treat TS patients.

CONCLUSION

TS is a fascinating condition both scientifically and clinically. The semivoluntary nature of tics makes them a good model for understanding human volition and impulse control. There has been significant research about this from neuroimaging and neurophysiological perspectives. As well, there has been some intriguing research into the potential role of neuroimmunological mechanisms in TS. Furthermore, the complex genetics involved in TS will require sophisticated and multifaceted approaches, such as those that consider gene-environment interactions and possibly epigenetic mechanisms, to unravel the heritability of TS. These patients present in highly variable ways, and they are consistently interesting in terms of their conditions and as individuals. The wide array of tools available to help them, from the simple and straightforward to more involved interventions, continues to evolve. Thus, the field of TS is a dynamic and fulfilling area of integration at multiple levels.

Schizophrenia

Matthias Weisbrod

Ute Pfüller

Daniela Roesch-Ely

Johannes Schröder

Schizophrenia is common, has high social and economic impact, manifests early—mostly during adolescence and early adulthood—and is frequently preceded by a premorbid pattern of rather unspecific but nevertheless handicapping symptoms that may be present for several years before clinical manifestation. A wealth of biological markers associated with schizophrenia has been identified in the fields of neurophysiology, neurochemistry, and neuroimaging. The endophenotype concept allows for the integration of these heterogeneous results with recent molecular genetic findings. However, none of the biological findings have proved to be of clinical value in respect to differentiate schizophrenia subtypes, to support differential diagnosis, or to fine-tune therapy. Diagnosis is still based on psychopathological features, and pharmacological intervention is the mainstay of therapy. However, individual psychotherapy, sociotherapy, and family interventions are gaining ground. In this regard, cognitive deficits are of particular interest since they represent the best-known predictors of functional outcome in schizophrenic patients. Treatment of cognitive deficits appears to improve the outcome of schizophrenia. However, despite progress in understanding schizophrenia and in terms of therapeutic approaches, more than one-third of affected people have a poor outcome, and no more than 20% have a good outcome.

With a lifelong prevalence of 1%–1.5%, and with 0.025%–0.05% of the total population in developed countries in treatment in any 1 year, schizophrenia is a common disease with high social and economic impact. Schizophrenia is equally prevalent in men and women; however, both age at onset and the course of illness differ between the sexes. Onset in men is earlier, with more than half suffering from schizophrenic symptoms before the age of 25, whereas peak age in women is 25–35, with a second peak at the beginning of the fifth decade. The second peak among women, with overall similar prevalence, seems to indicate some protecting influence of female sexual hormones (i.e., estrogen). The protective function of estrogen may also be involved in the more benign course in women with favorable functional and—especially—social outcomes. However, hormonal treatment has not yet been shown to have a beneficial effect.

Schizophrenia is considered a disease covering a spectrum of various disorders that differ with regard to etiologic factors, clinical course, and outcome. Bleuler (1857–1939), who coined the term “schizophrenia” in 1911, considered the plural form “schizophrenias” to be more appropriate. The term “schizophrenia” was widely accepted at the time and replaced Kraepelin’s (1865–1925) term “dementia praecox,” which emphasized the long-term deterioration after early onset. In diagnostic

matters, the United States has tended to follow Bleuler's conceptualization, whereas European countries favored Kraepelin's ideas, which has resulted in as much as twofold higher incidence rates of schizophrenia in the United States. However, with the introduction of the *DSM-II*, the U.S. diagnostic system has moved toward Kraepelin's ideas and the two concepts have merged. Today there are only subtle differences between the two diagnostic systems concerning schizophrenia.

The diagnosis of schizophrenia was highly influenced by the ideas of Kurt Schneider (1888–1967). Schneider distinguished between *Erstrangsymptome* (first-rank symptoms) and *Zweitrangsymptome* (second-rank symptoms), claiming first-rank symptoms to be more valuable for the diagnosis of schizophrenia. Schneider's ideas are still preserved in the actual categorical diagnostic systems. Another idea of Schneider's is still influential. In his opinion, schizophrenic symptoms arise from distinct cerebral lesions or dysfunctions. This assumption stimulated a wealth of neuropathological as well as structural and functional neuroimaging research. However, none of the numerous structural and functional findings that separate schizophrenic patients as a group from healthy controls has qualified as a diagnostic marker on an individual basis.

Although prevalence of schizophrenia is around 1% in most cultures and regions, some geographical pockets with high incidents of schizophrenia have been identified. These inconsistencies have been interpreted as supportive of an infective and/or genetic cause of schizophrenia. Family, twin, and molecular genetic studies clearly demonstrate the significance of genetic factors in the manifestation of schizophrenia. In general, the risk of developing schizophrenia is higher for members of families with one or more affected members and increases with the number of shared genes: it amounts to 10% in first-degree relatives of affected individuals, whereas it is only 5% in second-degree relatives. If both parents are affected, an individual's risk adds up to nearly 50% and reaches the risk of a monozygotic twin, whose twin sibling is affected. Adoption studies show that the risk of developing schizophrenia transmits with the genes, not with the social environment. The finding of a strong genetic contribution to schizophrenia was supported by recent studies that employed advanced molecular genetic methods. They found associations between several gene loci and the manifestation of schizophrenia. They also showed that schizophrenia is not caused by a single gene. In contrast, a number of genes seem to modulate the risk for schizophrenia to different extents and in different ways and even interact with each other. However, how genes

contribute to the manifestation of the illness is not yet fully understood.

Family-, adoption-, and twin studies show that genetic vulnerability manifests not in the manifestation of full-blown schizophrenia but also in related syndromes. These syndromes are known as schizophrenia spectrum disorders and include schizotypal personality disorder as well as affective and schizoaffective psychoses. Therefore, not just the illness schizophrenia as diagnosed according to diagnostic manuals seems to be inherited, but rather a heterogeneous and blurred phenotype with a specific vulnerability to schizophrenia is transmitted genetically. The manifestation of schizophrenia seems to rely highly on environmental factors. Thus the genes associated with schizophrenia constitute a dimensional rather than a categorical spectrum characterized by unspecific single symptoms and symptom clusters.

Findings from twin studies consistently show that only about half of monozygotic twin pairs are concordant for schizophrenia. These findings and the observation from adoption studies that—by existing genetic vulnerability—the interactions in fostering families modulate the individual risk of developing schizophrenia point to the importance of environmental factors to the manifestation of schizophrenia. Cumulative evidence from a large number of studies suggests that genetic factors are necessary in the sense that they create an elevated vulnerability but are not sufficient by themselves for the development of schizophrenia. Then again, a number of environmental risk factors have been consistently identified in a wealth of studies. Among these findings are the preponderance of winter births; urban environments; postnatal infections, in particular with toxoplasmosis; and aberrant transcription of elements related to the human endogenous retrovirus (HERV-W) family during manifestation of schizophrenia. Taken together, these findings lead to the hypothesis that both genetic and environmental factors are involved in the pathogenesis of the disease.

The most widely accepted conceptualization of the manifestation of schizophrenia, which integrates biological—including genetic—psychosocial, and environmental factors, is the stress-diathesis model. It postulates an interaction between factors constituting vulnerability (diathesis), which drives the symptoms of schizophrenia to develop (Zubin & Spring, 1977).

PSYCHOPATHOLOGY

Psychopathology of schizophrenia is characterized by its polymorphism in terms of the symptoms as well as the

course. Eugen Bleuler's distinction between fundamental or primary symptoms (*Grundsymptome*) and accessory or secondary symptoms (*akzessorische Symptome*) was very influential, as was Kurt Schneider's differentiation between first-rank symptoms and second-rank symptoms. The specificity and the prognostic relevance of these concepts are under critical discussion; nevertheless, they are of fundamental significance for our overall understanding of schizophrenic psychopathology. Primary symptoms according to Bleuler consist of affective disturbances, loosening of associations, ambivalence, and autism, whereas accessory symptoms include delusions, hallucinations, and catatonia. Bleuler conceptualized primary symptoms as related to the biological and etiological basis of schizophrenia. Accessory symptoms, in contrast, were thought to result from the primary symptoms. Kurt Schneider's first-rank symptoms comprise audible thoughts, voices arguing or discussing, voices commenting, somatic passivity experiences, thought withdrawal and other experiences of influenced thought, thought broadcasting, delusional perceptions, and all other experiences involving volition, made affects, and made impulses. Kurt Schneider considered first-rank symptoms in no way specific to schizophrenia but of pragmatic value in establishing a diagnosis, whereas second-rank symptoms, such as sudden delusional ideas, were rather unspecific. Schneider himself pointed out that schizophrenia may be present without first-rank symptoms and emphasized that somatic illnesses may show first-rank symptoms as well. He did not want to rigidly apply first-rank symptoms in the diagnosis of schizophrenia. Bleuler's and Schneider's ideas are still preserved in the diagnostic manuals currently in use for reliable diagnosis of schizophrenia: the *ICD-10* and *DSM-IV*.

The description of schizophrenic subtypes aims at reaching beyond schizophrenic symptoms. The *DSM-IV*, for example, defines five subtypes: paranoid type, disorganized type, catatonic type, undifferentiated type, and residual type. This differentiation is of some clinical value but is not overall satisfactory, since the subtypes in use (1) are not stable over the course of the illness, (2) do not closely correlate with prognosis, (3) do not predict responsivity to specific treatment, and (4) so far have not been shown to be associated with any common etiological mechanism.

In a number of influential papers, Nancy Andreasen (1985) delineated positive and negative symptoms—like loose associations, hallucinations, bizarre behavior, and increased speech or affective flattening, poverty of speech or speech content, blocking, poor grooming, lack of motivation, anhedonia, social withdrawal, cognitive

defects, and attention deficits. This differentiation has not only been supported in a wealth of studies but has also entered clinical practice as a comprehensive approach to describe the psychopathology.

COGNITIVE DYSFUNCTIONS

Cognitive dysfunctions form, along with positive and negative symptoms, a core feature of schizophrenia. Emil Kraepelin described features of the disorder that he thought reflected impairments in cognition and attention. He believed that these impairments were mediated by dysfunction of the frontal lobe. Even though cognitive deficits in the domains of attention, memory, and executive functions were well described, they only recently began to receive the attention of therapeutic approaches. This may be due to the more obvious and dramatic presentation of positive symptoms. Moreover, the introduction of chlorpromazine and other antipsychotic drugs in the 1950s, with their ability to improve positive symptoms, shifted the focus to this symptom domain. The realization that cognitive deficits are better predictors for functional outcome in schizophrenic patients than positive symptoms (Green, 1996) led to a renewed interest in the role, diagnosis, and therapy of cognitive deficits in this disorder. Cognitive dysfunction is common in schizophrenia; overall more than three-quarters of patients show clinical relevant impairments in at least two neuropsychological domains (Palmer et al., 1997). Cognitive impairments in schizophrenia are heterogeneous. In a catchment area-based population with schizophrenia ($n = 138$), Kelly, Sharkey, Morrison, Allardyce, and McCreadie (2000) found that 81% had significantly impaired memory, 49% suffered from impaired verbal fluency, 25% showed executive dyscontrol, and 15% had a significant global cognitive impairment, as assessed by Mini-Mental Status Examination (MMSE). Disturbed cognition is present in first-episode patients, seems to precede the first psychotic symptoms, stays relatively stable over the course of the disease, and does not necessarily correlate with the actual psychopathology.

COURSE OF SCHIZOPHRENIA

Sudden onset of schizophrenia without any premorbid signs and symptoms occurs but is rare. Characteristically, the symptoms begin in adolescence. Typically, the manifestation is preceded by a prodromal phase, which starts months, mostly even years, before the onset of

overt psychotic symptoms. Prodromal signs comprise unspecific somatic and vegetative symptoms; weakness; sleep disturbance; unmotivated mood swings; irritability; cognitive problems with, for example, decreased attention; and overall reduction in occupational, social, and personal activities. Concerning the early manifestation of schizophrenia, the long prodromal phase with impaired social and occupational performance in this critical life period spoils the overall outcome. It was shown that the duration of untreated psychosis has an impact on the overall prognosis. Programs aiming at timely diagnosis and early intervention have shown some success.

The prodromal stage is often preceded by premorbid personality traits, which are rather unspecific. A person who becomes schizophrenic may retrospectively be characterized by relatives as quiet, passive, submissive, and introverted. This person may have had no active social life and only few close friends. Mehl used the acronym SHAITU—submissive, hypohedonic, anxious, introverted, traumatized, and unlucky—to characterize these premorbid personality characteristics. There is a lot of evidence for developmental deficits preceding the manifestation of schizophrenia, like retardation in speech acquisition, delusional and hallucinatory experiences, disturbed coordination and motor functions, and impaired sensory functions. Some of these signs are aggregated in the concept of neurological soft signs (NSS), which have been shown to be a reliable finding in schizophrenic patients (Schröder et al., 1991). Prospective studies indicate that NSS increase with manifestation of the disease and follow its clinical course thereafter. Patients with a favorable course typically show a decrease of NSS with clinical stabilization while scores remain high in those who develop chronic schizophrenia.

After the first manifest episode of schizophrenia, there is often a period of gradual or complete recovery. Positive symptoms tend to become less severe with time; however, the socially debilitating negative symptoms may increase in severity. Overall, about 10%–20% of patients show a relatively good outcome, with almost complete and stable remission; one-third show episodic courses with complete or partial remissions during the interval; one-fourth show incomplete remissions; and one-fourth follow a chronic deteriorating course with lasting deterioration in baseline functioning. Overall, about one-fourth to one-third of affected individuals show nearly normal social functioning.

Most of schizophrenia manifests in the third decade of life. About one-fourth of cases begin after the age of 45. The onset of schizophrenia before age 10 is

rare. Early-onset schizophrenia with onset before the age of 18 is predictive for poor prognosis. It shows a more severe course and a worse outcome, specifically, a worse response to antipsychotic medication, poor social adjustment, more severe functional impairment, and higher socioeconomic dependence. Early-onset schizophrenia is also associated with a poor premorbid status and higher rates of negative symptoms. There is also evidence of etiopathogenetic differences depending on the age of onset: patients with early-onset schizophrenia more frequently present neurodevelopmental deficits and a lower pre-illness intellectual level. In addition, pre- and perinatal genetic and environmental disturbances are more common in patients with early onset. Other features pointing to bad outcome are subtle onset; poor premorbid social, sexual, and work histories; withdrawal; autistic behavior; comorbid drug dependency; family history of schizophrenia; and perinatal trauma.

ETIOLOGY

Schizophrenia is considered to be a disease covering a spectrum of various disorders that differ with regard to etiologic factors, clinical course, and outcome.

Stress-Diathesis Model

The most widely accepted concept on the manifestation of schizophrenia, which integrates psychosocial, environmental, and biological—including genetic—factors, is the stress-diathesis model. The stress-diathesis model postulates that the interaction between vulnerability and stressful environmental influences results in the manifestation of schizophrenia (Zubin & Spring, 1977). In addition, protective factors are thought to act against the manifestation of schizophrenia. Diathesis may arise from different biological factors like genetics, pre- and perinatal problems like malnutrition, infectious diseases during pregnancy, and birth complications. Diathesis may consist of psychosocial or further environmental factors or a combination. Stress can be biological or psychosocial; under discussion are life events, trauma, psychoactive drugs, infections, and other forms of organic diseases. Manifestation and symptomatology of schizophrenia are conceptualized to be the result of complex interactions between diathesis and development, psychosocial, and other environmental factors as well as individual attempts to cope with the arising problems. Numerous findings support the stress-diathesis model; however, causal connections between

specific vulnerability factors and their interactions with stress and cerebral dysfunctions are not satisfactorily understood yet.

Three Hit Model of Schizophrenia

The “three hit” model of schizophrenia was proposed by Keshavan (1999). It builds on the stress-diathesis model, integrates additional concepts, and relates them to a specific neurotransmitter hypothesis. In contrast to the quite unspecific diathesis-stress model, it generates testable predictions of relevance to pathophysiological research and therefore seems to be more suitable for research. It assumes the occurrence of disturbances in three critical time frames. These disturbances result in “hits” that promote the manifestation of schizophrenia and may interact with each other. The critical windows of vulnerability are represented by maturation periods of critical systems for information processing or cognitive functioning. Integration of knowledge about organization of information processing, as well as age-dependent development, allows us to understand how disturbances during vulnerable periods result in specific cognitive impairments and symptoms.

The assumed first hit refers to early neurodevelopmental models, which suggest a “fixed” early-life lesion interacting with brain maturation occurring later on. This first hit consists of pre-/perinatal insults from the second trimester of pregnancy onward, which influence processes of programmed cell death, neural migration, and/or synaptic proliferation. They are likely to manifest later in life as premorbid neurocognitive abnormalities. Some markers of early development are thought to indicate the occurrence of these putative insults (e.g., dermatoglyphic abnormalities in schizophrenic patients). The second hit refers to Feinberg’s (1982) hypothesis of abnormal periadolescent synaptic pruning. Exaggerated pruning during adolescence, which is conceptualized as the second critical window, may reduce neuronal modulatory capacity to handle normative academic, familial, and interpersonal demands and therefore may promote schizophrenia. The first hit may predispose the individual to excessive synaptic pruning and thus raise the risk of early onset. The third hit refers to a neurodegenerative process, which brings back Kraepelin’s concept of dementia praecox; the critical window is the early course of the schizophrenic illness. A “neurotoxic effect of psychosis” can develop from the association between poor outcome and the duration of untreated psychosis and the progression of brain volume reductions in schizophrenia over time. This neurodegeneration might be reflected by a deterioration of cognitive

functions leading to a deficit state in a substantial proportion of patients.

Psychosocial Factors

The wide acceptance of the stress-diathesis model emphasizes the need to identify individual, family, and social issues that may add up to vulnerability or foster stress. For example, schizophrenia is overrepresented in lower social classes. Since there are no differences between schizophrenic patients and control subjects regarding the social status of the original family, this finding may be caused by social drift of affected subjects due to loss of capabilities. Theories linking the manifestation of schizophrenia directly and causally to psychosocial factors have not been sustained. In particular, Harry Stack Sullivan’s view that schizophrenia may be caused by faulty, overly anxious mothering did not hold. The double-bind concept formulated by Gregory Bateson postulated dysfunctional familial interaction to be the cause of schizophrenia. Conflicting parental messages were thought to force the child to withdraw into psychotic states to escape irresolvable situations. However, the double-bind concept did not stand up to the empirical challenges.

In contrast, the correlation of personal interaction and several other psychosocial features with the risk of schizophrenic manifestation is well established. There is a lot of evidence that a kind of intrafamilial communication, which is characterized by high levels of criticism, hostility, and/or emotional overprotection from parents or other caretakers toward a schizophrenic person, is associated with an increased risk of relapse. This notion of expressed emotion (Leff & Vaughn, 1985) arose from the clinical observation of increased relapses in young schizophrenic patients who live in families showing high expressed emotion. There is no persuading evidence that expressed emotions or dysfunctional family interactions in general play a causative role in the development of schizophrenia.

Biological Factors

Neurotransmitters

It is clear that an imbalance of neurotransmitters is involved in the pathophysiology of schizophrenia. Of all neurotransmitters, dopamine has received the most attention in schizophrenia research. However, there is ample evidence for the involvement of other neurotransmitters as well. The focus on dopamine arose from several findings: dopaminergic substances like

amphetamine provoke, even in healthy subjects, psychosis-like symptoms. The antipsychotic effect of most antipsychotics is related to their affinity to dopamine type 2 (D2) receptors. The dopamine hypothesis of schizophrenia was formulated by Karlsson (1978). He postulated that schizophrenia results from high dopaminergic activity. The more refined varieties of this theory take the different dopaminergic type receptors into account and link the dopamine type 1 receptor specifically with negative symptoms. Moreover, there is evidence for a general dopamine imbalance with increased dopaminergic activity in the mesolimbic tracts but deficient dopaminergic activity in the mesocortical tracts. However, there are some caveats regarding the dopamine hypothesis of schizophrenia: (1) the dopaminergic imbalance has not yet been shown in untreated first-episode schizophrenic patients; (2) the therapeutic effect of dopamine antagonistic drugs needs several days to start; (3) dopamine antagonists are effective in treating virtually all psychotic and severely agitated patients, regardless of diagnosis; (4) it seems that dopaminergic neurons increase their firing rates in response to long-term exposure to dopamine antagonistic drugs; and (5) substances with only marginal dopamine antagonistic activity may nevertheless be potent antipsychotics (e.g., clozapine).

The efficacy of clozapine in the treatment of schizophrenic symptoms, together with the observation that a single neuron may contain more than one neurotransmitter and may make use of more than one neurotransmitter receptors, led to consideration of the potential role of other neurotransmitters.

The assumption that serotonin plays a role in schizophrenia is supported by several findings: (1) hallucinogenic substances like lysergic acid diethylamide (LSD) act as agonists on serotonergic receptors (5-HT₂); (2) many of the second-generation antipsychotics show potent serotonin-related activities; and (3) a polymorphism of the 5-HT_{2a} gene has been identified as a genetic risk factor for development of schizophrenia.

There is also evidence for the involvement of glutamate in schizophrenia: phencyclidine (PCP) as well as ketamine—both NMDA-receptor-agonistic substances—provoke not only schizophrenic positive but also schizophrenic negative symptoms. Besides the direct involvement via its excitatory influence on neurons, more complex involvement via glutamate-induced neurotoxicity has been discussed.

Since long-term administration of antipsychotics decreases the activity of noradrenergic neurons and it has been observed that the noradrenergic system modulates the dopaminergic system, the causative role of norepinephrine is also under discussion.

Neuropathology

The failure of neuropathologists in the early 20th century to attribute the basis of schizophrenia to specific brain lesions led to the classification of schizophrenia as a functional disorder. However, with the development of more sophisticated neuropathological methods, subtle alterations have been demonstrated. The major brain areas implicated in schizophrenia are the limbic structures, the frontal lobes, the basal ganglia, the thalamus, the brain stem, and the cerebellum, with most consistent findings for the limbic system and the basal ganglia. For the limbic system, postmortem studies have demonstrated a decrease in the size of the amygdala, the hippocampus, and the parahippocampal gyrus. Moreover, disorganization with disturbed cell orientation in the hippocampus has been found. In respect to Keshavan's three-hit model, this may represent the result of a first hit.

Although reports about neuropathological findings concerning the basal ganglia are inconclusive, an increase in the number of D2 receptors in the caudate, the putamen, and the nucleus accumbens has been reported consistently. However, there is evidence that this increase may be secondary to antipsychotic medication.

Overall, neuropathological findings point to subtle anomalies in schizophrenia, especially concerning organization of cells and regional cell loss. However, these findings are not completely consistent and do not qualify as diagnostic markers on an individual basis.

Neurophysiology

A high proportion of schizophrenic patients display brain-wave patterns with abnormal features, among which the generalized patterns of increased delta, increased theta, and increased beta as well as decreased and slowed alpha activity are the most robust findings. Lower levels of alpha activity may reflect atrophy of the thalamus, where the pacemaker cells of the alpha rhythm are hypothesized to be located. On the other hand, higher levels of theta activity may reflect hippocampal theta spiking. In addition, dysrhythmic and epileptic elements are seen in spontaneous EEG (electroencephalography) in schizophrenic patients. Moreover, physiological spontaneous modulation and the reactivity in response to external stimuli have been found to be reduced in persons suffering from schizophrenia. Altogether, the pathological findings are predominantly present on left hemispheric leads. They are more pronounced in non-medicated than in medicated

subjects and therefore not secondary to antipsychotic medication.

Overall, electrocortical anomalies turned out to be, by themselves, neither necessary nor sufficient to determine the presence of the illness, as the most deviant features observed in schizophrenic patients may also show up at times in normal, healthy subjects. In consequence, a satisfactory specificity of electrocortical anomalies with respect to schizophrenia diagnoses appears to be achievable, if at all, only on the basis of a multivariate configuration of EEG features.

Event-related potential (ERP) is an EEG change that is time locked to sensory, motor, or cognitive events. ERPs provide a safe, non-invasive approach to the study of psychophysiological correlates of mental processes. Since ERPs represent mental processes, which are thought to be disturbed in schizophrenic patients, they promise higher sensitivity and specificity than spontaneous EEG. Several ERP components have been demonstrated to be anomalous in schizophrenia, like P50, MMN (mismatch negativity), CNV (contingent negative variation), N100, P300, and N400. The two ERP components that have received the most attention are P300 and P50.

P300 is the most thoroughly studied cognitive ERP component of all. It consists of a positive ERP component with maximal amplitude over the centroparietal cortex peaking about 300–600 msec after presentation of a stimulus requiring a covert or overt response. Since the first report of P300 amplitude reduction in schizophrenic patients by Roth and Cannon (1972), the finding of reduced P300 amplitude in schizophrenic patients has been replicated numerous times. Since P300 depends on subjective certainty in the detection of relevant events, the P300 abnormalities of schizophrenic patients may arise from impaired early sensory processing as well as from attentional deficits, both of which are known to be present in schizophrenic patients (Goldberg, Gold, & Braff, 1991). In addition to the robust findings of generalized P300 amplitude reduction, a P300 asymmetry—that is, smaller left temporal amplitudes—has been found in several studies, but not in all (Weisbrod, Winkler, Maier, Hill, Thomas, & Spitzer, 1997). This asymmetry has been shown to be associated with left hemispherical structural pathology (McCarley et al., 1993) and present in schizotypal personality disorder as well. Several studies also found delayed P300 activity in schizophrenic patients, but these findings were not entirely consistent. Unfortunately, the usefulness of P300 amplitude reduction as a marker for schizophrenia is somewhat limited, since P300 amplitude reduction is not specific to schizophrenia and has

been demonstrated in other psychiatric illnesses as well. Moreover, P300 reduction in schizophrenia patients is robust on group analysis but not suitable for individual diagnosis, since significant overlap with healthy subjects has been observed.

Numerous researchers have shown that the auditory evoked P50 in response to two identical auditory stimuli separated by a short pause lead to a systematic decrement of the response to the second stimulus by activation of an inhibitory system (Adler, Pachtman, Franks, Pecevic, Waldo, & Freedman, 1982). This reduction in amplitude is considered to reflect a basic neurophysiological process called sensory gating, which protects the individual against sensory or information overload. Schizophrenic patients' inability to adequately suppress the second of two identical stimuli has been viewed as the physiological correlate of patients' perception of being flooded by sensory impressions, their hyperawareness of background noises, and their difficulty concentrating. There is interest in gating because two recent meta-analyses have shown disturbed gating in schizophrenia with high effect sizes (Bramon, Rabe-Hesketh, Sham, Murray, & Frangou, 2004; de Wilde, Bour, Dingemans, Koelman, & Linszen, 2007). Moreover, recent studies suggest that impaired information processing is related to negative symptoms (Louchart-de la Chapelle et al., 2005), including cognitive impairment. Thus measures of sensory gating may provide an objective tool for establishing the diagnosis of schizophrenia and for testing the effects of new medications directed against cognitive and negative symptoms. However, reliable measurement of the P50 suppression is technically challenging and its clinical usefulness is still limited.

Electrophysiological measurements are of interest concerning genetic vulnerability of schizophrenia. Evidence from several studies suggests that interindividual differences of spontaneous human brain-wave patterns (EEG) are predominantly determined by genetic factors. In particular, the within-pair EEG concordance of monozygotic twins has been found to be typically as high as $r = 0.81$ across channels and frequency bands, and thus comparable to that between repeated assessments on the same individual (typically $r = 0.83$). Our investigations on monozygotic twins discordant and concordant for schizophrenia have yielded significantly reduced within-pair EEG concordance for both the pairs discordant as well as the pairs concordant for schizophrenia. We could therefore show that EEG anomalies associated with schizophrenia manifested differently in the monozygotic twins concordant for schizophrenia. EEG anomalies are likely to represent the effect of

nongenetic pathologic processes that evolve independently in the twins' genetically identical brains once the illness begins to progress.

Twin and family studies in healthy subjects also point to a genetic basis of the P300 component: all studies performed on healthy twins demonstrated a high level of heritability and greater similarities in P300 features in monozygotic twins than in dizygotic twins or unrelated individuals. P300 abnormalities were found in patients with schizophrenic spectrum disorders, in unaffected first-degree relatives of schizophrenic patients, in offspring of schizophrenic patients, and in non-affected twins of discordant monozygotic twin pairs. Moreover, the gating deficit also seems to reflect a genetic trait in schizophrenia. Therefore, electrophysiological research seems to be useful for shedding light on the genetic vulnerability and the differentiation between genetic and environmental factors involved in the pathogenesis of schizophrenia.

Neuroimaging

The first brain-imaging data demonstrating ventricular enlargement in schizophrenia were generated in 1927 through the use of pneumoencephalography. Systematic brain-imaging data were gathered in the 1950s when Huber (1961) demonstrated third ventricular enlargement in 72.6% of 212 chronic schizophrenic patients versus 12.1% of 1,294 control subjects. The finding of lateral and third ventricular enlargement, together with some degree of reduction in cortical volume, was confirmed by a large body of computed tomography and magnetic resonance (MR) studies later on. The imaging findings of reduced cortical volume concerns mostly frontal and temporal brain regions, the hippocampal-amygdala complex, the parahippocampus, part of the basal ganglia, the thalamus, and the cerebellum and are therefore in agreement with the postmortem neuropathological findings. Pronounced brain tissue losses seem to be more present in male than in female patients and are related to higher levels of negative symptoms and predict unfavorable outcomes. The presence of structural abnormalities was also found to be correlated to neuropsychiatric impairment, increased neurological signs, and sensitivity to extrapyramidal symptoms due to antipsychotics. The question of whether decreases in the amount of brain tissue loss in schizophrenia are due to abnormal development or to degeneration remains unanswered. However, studies involving twins and relatives as well as longitudinal examinations pointed to genetic as well as disease-specific influences with some kind of degenerative processes acting on brain structures. Longitudinal studies showed progression of

structural deficits, especially in patients with unfavorable courses. However, these findings are inconclusive and relationships between psychopathology and course of illness with specific morphological signs are not generally accepted yet.

The use of brain imaging for diagnostic purposes is somewhat limited since the abnormalities found in schizophrenic patients have been similarly reported in other psychiatric illnesses like mood disorders, alcohol-related disorders, and dementias. Moreover, the difference between affected and unaffected persons is variable and quite small. Magnetic resonance spectroscopy and positron emission tomography have revealed some interesting findings; however, the results are rather inconsistent, which makes these methods far from usable for clinical use.

Functional Neuroimaging

Functional-imaging studies usually record the regional blood flow or glucose utilization, both of which represent local neuronal activity. Because of its higher availability and lower costs, and for safety reasons, functional MRI is used more often than PET (positron emission tomography) and SPECT (single-photon emission computed tomography). However, for particular matters of interest, PET and SPECT are still useful. Numerous studies show a dysfunctional activation of frontal cortical areas, especially in tasks employing executive functions, like the Wisconsin Card Sorting Test or the n-back. Ingvar and Franzén (1974) were the first to report this dysfunction; they coined the term "hypofrontality." Since then hypofrontality has been demonstrated in several independent studies, although some data demonstrate that it consists of not a mere hypofrontality but a more general dysfunctional activation of the frontal brain areas. Hypofrontality seems to be somehow related to negative symptoms (Schröder, 1997).

PET and SPECT using specific tracers are suitable for exploring the number and affinity of distinct receptor types in specific brain regions. These studies have demonstrated the connection between the extrapyramidal side effects of antipsychotic drugs and the amount of D2 receptors blocked by the specific drugs. It became obvious that side effects occur when more than 70% of receptor activity is blocked. Some studies have explored the dopamine receptors in first-episode and drug-naïve persons. These studies did not reveal reliable and persuading differences in comparison to healthy control subjects and thus challenge the dopamine hypothesis of schizophrenia.

Homogenous structural lesions of a significant amount qualifying as diagnostic markers seem not to be pres-

ent in schizophrenia. Rather subtle differences are thought to characterize the brain dysfunctions that underlie schizophrenic psychopathology. Although functional neuroimaging has revealed a wealth of data that advance our understanding of schizophrenia enormously, there is no valuable diagnostic marker on the horizon yet.

DIAGNOSIS

Diagnosis of schizophrenia is based on the information given by the patient, his or her relatives and significant others, and observations of the patient's behavior and the interpretation of the interactions between patient and examiner. In order to establish reliability, diagnosis is based on categorical diagnostic systems. The World Health Organization's *ICD* (the most recent edition of which is the *ICD-10*) and the American Psychiatric Association's *DSM* (the most recent edition of which is the *DSM-IV*) are the most commonly used ones. Reliability can be enhanced by structured or semi-structured diagnostic interviews. Both the *ICD* and the *DSM* schizophrenia diagnoses make use of Schneider's distinction between first-rank and second-rank symptoms. Both introduce a time criterion, demarcate schizophrenia from other diseases, and describe distinct subtypes. Despite the enormous increase of knowledge in the realms of neurotransmitter systems, neurophysiology, cognitive functions, brain activation, and genetics, no objective diagnostic markers that prove or at least support the diagnosis of schizophrenia are yet available. This may be due to the heterogeneity of schizophrenia or to the quite subtle common disturbances underlying schizophrenic psychopathology. However, technical examinations are useful for excluding competing diagnoses. For example, EEG may be used to explore epilepsy, especially temporal lobe epilepsy; computed tomography and MRI are crucial for excluding brain neoplasms or trauma; and lumbar puncture and the analysis of cerebral fluid allow us to exclude the possibility of infectious diseases.

Like somatic examination, neuropsychological assessment does not prove or exclude the diagnosis of schizophrenia. However, neuropsychological evaluation is important for planning therapeutic strategies. It gives some hints to the patient's prognosis, as cognitive dysfunctions are the best predictors for long-term functional outcome. A neuropsychological battery of clinical value should (1) record all relevant neuropsychological domains, (2) use tests with high sensitivity and reliability, (3) allow for repeated measures in order to observe the course, (4) employ tests with comparable difficulty

that are easy enough for severely ill patients but difficult enough to get reasonable norm values from healthy control persons, (5) be applicable in a reasonably short period of time, (6) record subjectively perceived cognitive problems and the individual weighting by the patient, and (7) relate the findings to the person's everyday life activity. In addition, motivation and affective state should be recorded, and their influence on the test results weighted. The premorbid state and the familial and sociocultural background should be known and taken into account in the interpretation of the results. Each neuropsychological test should focus on one single cognitive domain but should also be valid and address capabilities relevant to everyday life. The inclusion of information from relatives improves validity and reliability. The task force CNTRICS (Cognitive Neuroscience Treatment Research to Improve Cognition in Schizophrenia) is on its way to compiling a neuropsychological test battery that meets these requirements.

TREATMENT

Schizophrenia is a complex disorder that manifests early in life—mostly during adolescence—and is frequently preceded by a premorbid pattern of rather unspecific but nevertheless handicapping symptoms that may be present for several years before diagnosis is established. At the first psychotic episode, psychosocial consequences and coping behavior are already present. Therefore, treatment has to be aimed at psychotic symptoms as well as at the psychosocial consequences of the illness even at the first episode. Moreover, cognitive symptoms should be taken into account. They often precede the first psychotic episode and are the best predictor of long-term functional outcome. Schizophrenia affects a person with a unique personality and concerns not only the affected person but the familial system as well. Treatment of schizophrenic persons has to address all these domains, and the clinicians administering treatment must be aware of their interactions.

In the acute psychotic episode there is an emphasis on the patient's safety and care for basic needs; hospitalization and treatment with drugs may predominate. However, it is important to realize the influence of the therapeutic approach during the acute state on the therapeutic relation and the long-term cooperation of the affected patient as well as the relatives. When acute symptoms fade, psychotherapeutic, cognitive, and psychosocial measures become more prominent. These measures should refer to the individual patient's specific resources and problems and aim at good long-term

functional outcomes. They should be planned in cooperation with the patient and the patient's caretakers.

Somatic Treatment

Psychopharmacological Treatment

Antipsychotics. Antipsychotics, which were introduced in the early 1950s, have revolutionized the treatment of schizophrenia. Antipsychotic medication is crucial to the treatment of the acute schizophrenic episode but is also important in the long-term treatment (for a meta-analysis, see, e.g., Thornley, Adams, & Awad, 1997). Antipsychotics are especially effective in treating positive symptoms. Unfortunately, the evidence of an effect on negative symptoms and cognitive impairments is far less persuasive. Moreover, antipsychotics can have annoying and even serious side effects, especially Parkinson's-like symptoms and tardive dyskinesia. Recently progress has been made in so-called second-generation antipsychotics, which cause fewer extrapyramidal side effects (although this has been challenged by two recent major studies; see Jones et al., 2006 and Lieberman et al., 2005). However, the initial expectation that second-generation antipsychotics may be more effective at treating negative or cognitive symptoms did not hold true. Clozapine is the only antipsychotic drug for which superiority has been shown for some aspects: clozapine prevents suicides in schizophrenic patients and may be effective in patients who do not respond to other drugs. It has also been shown that patients suffering from tardive dyskinesia may benefit from clozapine. However, the clinical value of clozapine is limited due to its association with agranulocytosis, which necessitates frequent and reliable monitoring of blood indexes. Thus the choice of an antipsychotic drug for an individual patient is driven more by expected side effects, pharmacokinetic as well as pharmacodynamic aspects, and cost than by the specific characteristics or effectiveness of different antipsychotics.

In the acute state, most patients respond to repeated doses of an antipsychotic. However, the antipsychotic effect does not show up immediately but needs several days to occur. Although the usefulness of antipsychotics for treatment of acute psychotic states is widely accepted, their role in preventing relapse is far more controversial. It is well established that long-term antipsychotic therapy considerably reduces the risk of relapse during the first 2 years after an acute episode. After discontinuation of antipsychotic treatment during the first year after a first schizophrenic episode, 80% of patients suffer relapses; discontinu-

ation in the second year results in relapse in 40% of patients. Therefore it is reasonable to advise persons following first episodes to continue antipsychotic treatment for at least 2 years. For patients who have experienced relapses in the past, the risk of acute psychotic symptoms after discontinuation is even higher. If acute psychotic states are shadowed by suicidal or dangerous aggressive behavior, lifelong antipsychotic treatment should be considered and discussed with the patient. However, it should be kept in mind that a reasonable percentage of patients achieve stable remission without antipsychotic long-term treatment and that about one-third of patients on antipsychotics nevertheless relapse. Unfortunately, there are no markers for an individual prognosis. Moreover, implementation of antipsychotic treatment upon early signs of deterioration was not shown to be successful in preventing relapses (Gaebel, 1994; Jolley, Hirsch, Morrison, McRink, & Wilson, 1990).

Concerning the chronic character of schizophrenia and the importance of self-management, the cooperation between the patient and his or her caretakers is of considerable importance. Therefore, the establishment of a stable therapeutic relationship, education of the patient and the patient's caretakers about schizophrenia, acceptance of the patient and his or her relatives as competent partners, the consideration of the patient's complex needs and therefore the family's support in different domains are crucial.

Other Psychopharmacological Drugs. Benzodiazepines are used in combination with antipsychotics in the acute phase to reduce anxiety and to achieve sufficient sedation. They are especially useful for the treatment of catatonic stupor. Moreover, in patients with insufficient response to antipsychotics, the coadministration of benzodiazepines has been shown to be helpful, and some patients are reported to have responded to high dosages of diazepam alone. However, the risk of dependency and the possibility of exacerbated psychotic symptomatology after withdrawal from benzodiazepines limit the clinical value of such a therapeutic strategy.

Antidepressant drugs are useful in treating depressive symptoms, which are present in the majority of schizophrenic patients. There are some hints that antidepressant drugs acting on the serotonergic system may alleviate negative symptoms.

If an adequate and long-enough treatment with antipsychotics has been unsuccessful, adjuvant medication like lithium or anticonvulsant drugs may be indicated.

Cognitive deficits in schizophrenia are the best predictors for functional outcome. Based on what is

known about the neurotransmitter systems modulated by the second-generation antipsychotic drugs, these drugs were expected to outperform the classical antipsychotics in terms of their ability to improve cognitive functioning. However, since second-generation antipsychotics did not show the expected positive impact on cognition, pharmacological treatment of cognitive deficits in schizophrenia remains challenging. There have been efforts to address cognitive symptoms, specifically through the add-on use of substances that directly influence cognitive processes—so-called cognition-enhancing drugs. Cognitive enhancers should improve more than one cognitive domain and have an impact on everyday life. Research on substances modulating the dopaminergic, cholinergic, noradrenergic, glutamatergic, GABAergic, serotonergic, and cannabinoid systems as well as antidepressant drugs, psychostimulants, anti-dementia medications, and even caffeine is ongoing.

Antipsychotics have changed the treatment of schizophrenia considerably. They constituted the first treatment strategy to act directly on schizophrenic symptoms. However, antipsychotics are not quite effective in respect to negative and cognitive symptoms, they do not solve the social problems of schizophrenic patients, and they are not always well accepted by patients and the patients' caretakers. Schizophrenia is a complex disorder that requires the combined use of psychopharmacological and psychosocial interventions. Psychosocial interventions should be carefully integrated into the drug treatment regimen and should support it, and vice versa; that is, medication should support and not hinder the psychosocial interventions (e.g., medication should not cause inappropriate sedation).

Other Somatic Treatments. For patients who for any reason (e.g., pregnancy) are not able to take antipsychotics, some patients with insufficient response to antipsychotics, and especially catatonic patients, electroconvulsive therapy may be indicated. Other somatic treatments like transcranial magnetic stimulation, which may be able to reduce specific symptoms like acoustic hallucinations, are not in regular clinical use yet.

Psychotherapeutic Treatment

During the acute psychotic episode, control of positive symptoms; agitated, disorganized, and inappropriate behavior; and suicidal or homicidal ideations require the use of antipsychotics and sometimes other drugs to stabilize the patient. Even if the patient's safety and

care for basic needs usually dominate the therapeutic measures, it is crucial to establish a reliable and as faithful as possible relationship with the patient and the patient's caretaker. The relevance of psychotherapeutic and psychosocial treatment increases as the acute episode fades out.

For the psychotherapeutic approach, some basic elements are of importance. Since psychotic patients are often anxious and suspicious, the clinician's approach toward the patient has to be straightforward, transparent, nonthreatening, and trustworthy. Because of patients' cognitive problems, information should be provided in an unambiguous, clear, and structured manner and address matters involving the patient's immediate needs. First of all, the clinician should focus on the immediate situation and identify and avoid potentially troublesome situations. Overstimulating actions and gestures should be avoided, the patient's affect should be calmed down, and the emotional intensity of sessions should be controlled. Establishing a relationship with the patient is a difficult matter and flexibility can be essential to the creation of a working alliance.

Independent of the specific psychotherapeutic approach used, strengthening the patients' self-esteem and understanding and accepting his or her psychotic experiences supports the patient as he or she gains control over psychotic symptoms. Adequate and fair appraisal of the changes in the patient's life due to the manifestation of the illness is helpful for stabilizing the patient's self-esteem. Realistic plans concerning the patient's life prospects may be crucial to prevent suicidal ideations. Cooperation with the patient's caretakers—if possible—is of high value.

There is ample evidence that individual psychotherapy is helpful and beneficial to the pharmacological treatment of schizophrenia. The types of therapies that have proved to be useful include supportive psychotherapy, insight-oriented psychotherapy, behavior therapy, and especially cognitive-behavioral therapy.

Cognitive-behavioral strategies often are based on the stress-diathesis model and focus on stress-generating factors. They aim at improved management of symptoms (e.g., persistent acoustic hallucinations) and support the patient in developing suitable coping strategies. Helping the patient develop an understanding of the illness is another target in order to enhance adherence.

Concerning the meaning of cognitive symptoms for long-term prognosis, several programs that aim at the improvement of cognitive functioning and at the achievement of "cognitive remediation" have been developed. It has been demonstrated that improvement of cognitive functions is possible in schizophrenic patients

and that improved cognitive functioning results in favorable outcomes. Furthermore it has become obvious that cognitive training has to start with a precise diagnostic of individual cognitive deficits and strengths so that the deficits' impact on everyday life can be analyzed and has to take into account the individual's coping strategies. Cognitive training has to be embedded in an overall treatment strategy, should be of sufficient duration and frequency, and should include active transfer from training to everyday life. In particular, for the integrated psychological therapy (IPT), beneficial effects for schizophrenic patients were demonstrated. IPT was developed by Brenner in 1976 and has since evolved (for a recent overview, see Müller, Roder, & Brenner, 2007). This method has obtained favorable effects not only in neurocognition but also in social behavior and psychopathology. Moreover, patients continue to experience the benefits of IPT over treatment as usual even after the actual treatment is discontinued.

Family-Oriented Therapies

The starting point for family-oriented therapies is the acknowledgement that families are extremely stressed by the psychotic illness of a family member. No family is prepared to shoulder the enormous burden that arises when a member is affected with schizophrenia. Prodromal symptoms are disturbing, and psychotic symptoms distract and shock family members. Psychotic behavior may generate helplessness, confusion, and even sadness, anger, and hostility. These feelings may manifest in hostile behavior toward the affected family member, maladjusted criticism, or overprotective behavior, which comprises the patient's autonomy. This may result in unfavorable outcomes and relapses. A number of studies demonstrate that family-oriented therapies are especially effective in reducing psychotic relapses not only for short periods but also over the longer term (Penn & Mueser, 1996). Moreover, the quality of life of both patients and relatives is enhanced by family-oriented interventions. Providing relatives with education and information has been demonstrated to be of particular usefulness. The long-range implementation of stress-reducing and coping strategies that enable families to support patient as they gradually reengage in activities is of particular importance.

SUMMARY

It is unlikely that schizophrenia describes a single disease. It is far more likely that schizophrenia comprises

a variety of distinct disorders that present with somewhat similar symptoms but are different in cause and outcome. The past years have brought major advances in the understanding of the genetic backgrounds of schizophrenia, the brain areas involved in the disease, and the affected neurotransmitter systems. Nevertheless, the problem of heterogeneity has not yet been solved. Some progress has been made in respect to therapeutic approaches. A new generation of antipsychotics with fewer side effects has been introduced, more specific psychotherapeutic strategies have been developed, early detection and intervention strategies have been realized, and specific models of social interventions have been implemented. Despite our progress in understanding schizophrenia, more than one-third of affected people have a poor outcome, and only 10%–20% have a good outcome. This is of particular significance since schizophrenia manifests early—mostly during adolescence—and is frequently preceded by a premorbid pattern of rather unspecific but nevertheless handicapping symptoms that may be present for several years. This burdens not only patients but also relatives and results in enormous costs. The ongoing research on how the brain works and how the brains' work may fail is on the way to yielding more specific diagnostic tools and may result in innovative therapeutic approaches. Some of them will stand up to clinical tests and improve the everyday lives of those affected with schizophrenia.

Cognitive-Behavioral Therapy: Theory and Practice

Eduardo Keegan
Paweł Holas

THE HISTORY AND EVOLUTION OF COGNITIVE-BEHAVIORAL PSYCHOTHERAPY

Researchers and clinicians argue about what the exact scope of cognitive-behavioral therapy (CBT) is. There are a number of current therapies that can be described as CBT, as they all share the assumption that thinking (cognition) mediates behavior change, and that changes in thinking lead to behavior and mood modification. Broadly speaking, the evolution of CBT can be divided into three or, as some claim, four stages:

- (1) Independent emergence of behavior therapy in the United States, South Africa, and the United Kingdom in 1950–1970 (first wave of CBT);
- (2) The beginning of cognitive therapy in the United States in the 1960s and 1970s (second wave);
- (3) Further development and merging with behavior therapy into cognitive-behavioral therapy, with momentum in the 1980s and ongoing remarkable achievements;
- (4) Development of the so-called third wave of CBT, with a primary emphasis on changing the function

of cognitions instead of changing their content, during the last 10–15 years.

The Emergence of Behavior Therapy

Cognitive-behavior therapy grew out of traditional behavior therapy, which was regarded as the first generation of scientifically based psychotherapy. It was an innovative approach based on but differing from the rather radical perspective of behavioral theorists such as Skinner and Watson. The major contributors to the beginning of behavior therapy were Joseph Wolpe (1958) in South Africa, who formulated the theory of reciprocal inhibition and introduced empirically validated fear-reduction treatment, namely, systematic desensitization, for phobias and anxiety, and, in the United Kingdom, Hans Eysenck (1952, 1960), who provided the theoretical basis and rationale for behavior therapy and was famous for his severe criticism of psychoanalysis and its claims. In a 1952 review, he claimed to find psychoanalysis to be no more effective than no treatment at all. Eysenck rejected the theory that neuroses are caused by unconscious (sexual) conflicts and that symptoms of neurosis are defenses against distress that would otherwise be impossible to bear. Instead, he hypothesized that if one gets rid

of the symptoms, he or she can rid of the neurosis (Eysenck, 1960). In the United States, Ogden Lindsley (1956) used operant techniques in working with schizophrenic patients.

Behaviorists who greatly influenced the development of cognitive therapy are Albert Bandura and Donald Meichenbaum. Bandura (1977a, 1977b) developed several important ideas, including social learning theory and the concepts of expectancy of reinforcement, self- and outcome efficacies, modeling, and vicarious learning. One of his achievements was proving that a perceived reinforcer was more reinforcing than an actual reinforcer that was not perceived to be reinforcing and, furthermore, that an individual does not have to be directly reinforced to execute an action to make it occur; it can be sufficient to observe another person being reinforced for this behavior. This research indicated that the behavioral assumption of an automatic connection between reinforcer and response might not be necessarily correct and that some internal processes may mediate this connection. Meichenbaum discovered that when people talk to themselves, this private speech functions as a significant control of behavior. He observed that schizophrenic patients who engaged in self-instruction to “talk healthy” demonstrated superior task performance on a variety of measures. He developed self-instructional training, in which he used graduated tasks, cognitive modeling, coping statements, and self-reinforcement (Meichenbaum & Goodman, 1971). He is considered to be one of the pioneers of CBT; however, his ideas were behavioral in nature because he claimed that behavior must be changed first, and then internal dialogue.

The main distinction between cognitive and behavioral therapies lies in the incorporation of the mediational perspective, that is, cognition mediates behavioral and emotional change, in the former into the understanding of emotional disturbances, a process that took place in the late 1960s and 1970s on the basis of Aaron T. Beck’s (1963, 1967, 1979) work on depression. Although the behavioral approach was still the dominant perspective at that time, there was growing awareness that the strict stimulus-response model of behavior is not comprehensive enough to account for all human behavior (Mahoney, 1974) and that some clinical problems such as depression and obsessional thinking cannot be effectively treated without cognitive interventions.

At the same time, there continued to be criticism of psychoanalysis. Behaviorists like Wolpe were strongly influenced by the empirical standards and ideas of Karl Popper, who claimed that psychoanalysis is unfalsifiable and hence outside science.

The Emergence of Cognitive Therapy

Cognitive therapy developed out of research on depression by Aaron T. Beck (1963, 1964), an American psychiatrist working at the University of Pennsylvania. Beck was trained in psychoanalysis and tried to validate the psychoanalytic concept of anger turned to the self as a cause of depression. By examining the stream of thoughts and dreams of depressed patients, Beck discovered that the main theme is not anger but defeat and loss. His clinical observations and experimental findings showed a consistent negative bias in how depressed patients processed information. Beck sought to develop cognitive interventions that sought to ameliorate patients’ suffering from depression and other emotional problems by helping them identify, examine, and modify the distorted and maladaptive thinking patterns underlying their problems. Cognitive therapy is based on the “rationale that an individual’s affect and behavior are largely determined by the way in which he structures the world” (A.T. Beck, Rush, Shaw, & Emery, 1979, p. 3) and that therapeutic change can be obtained through the utilization of techniques designed to “identify, reality test, and correct distorted conceptualizations and the dysfunctional beliefs (schemas) underlying these cognitions” (p. 4). In Beck’s theory, cognitions play a crucial role as they organize and regulate all other functions (A.T. Beck, Freeman, et al., 1990). The organism needs to process information in an adaptive way in order to survive. Cognition involves the process of identifying and predicting relations between a person and objects and events, so then adaptation to environmental demands is necessary. The key concept in Beckian cognitive therapy is schema, which is a meaning-making cognitive structure made up of tacit assumptions that construct interpretations of the self and the world, organize experiences, and guide behavior. Schemas are involved in screening, coding, and evaluating information (A.T. Beck, 1964), and they are usually established in early childhood. They may include rules about one’s personal, occupational, familial, or cultural activities, and they have cognitive, affective, motivational, and action-corresponding subschemas. Furthermore, schemas can be categorized as active to inactive, dormant or latent, and impermeable to permeable (A.T. Beck et al., 1990). They function outside people’s awareness, but their products—specific thoughts and images—are accessible. He called these products automatic thoughts to reflect the way they are experienced as spontaneous, habitual, and objective-like. Automatic thoughts organize a person’s emotional and behavioral reactions to specific situations and are

usually unrecognized, unless the person is instructed to search for them.

Techniques developed by Beck that aim to modify cognitions, ranging from how to attend, identify, and monitor automatic thoughts to how to challenge them and distinguish between appropriate and maladaptive cognitions, are most commonly used and are the key techniques in cognitive therapy.

Beck's cognitive therapy has undergone various modifications over the years and has been extended to most of psychiatric disorders listed in manuals and other difficulties. These include anxiety and phobias (A. T. Beck & Emery, 1985), marital problems (A. T. Beck, 1988), personality disorders (A. T. Beck et al., 1990), substance abuse (A. T. Beck, Wright, Newman, & Liese, 1993), suicide (Freeman & Reinecke, 1993), crisis management (Dattilio & Freeman, 1994), bipolar disorders (Basco & Rush, 1996), and anger (A. T. Beck, 1999). Although these adaptations have changed the focus and broadened tools of cognitive therapy, their theoretical assumptions remain the same as in Beck's original model.

Concurrent with Beck's research was the work of Albert Ellis (1958), the second pioneer of cognitive psychotherapy, who elaborated a method that he originally described as rational psychotherapy. Over the years he modified this strictly cognitive therapy and included more emotional and behavioral techniques, so then rational psychotherapy expanded into rational-emotive therapy, and then rational-emotive behavioral therapy. Similar to Beck, he focused on patients' thoughts and beliefs, proposed more active dialogue with them rather than passive listening, and included behavioral assignments and exercises in treatment programs (Ellis, 1962). He developed the A-B-C model, in which emotional consequences (C) are considered to be caused by beliefs (B) about events (A), not by the events themselves. The patient can modify these emotional consequences by "vigorously disputing" the beliefs (B) about the events or the situation (A). One of Ellis's major contributions was the distinction between rational and irrational thinking. He identified more than 10 basic types of irrational beliefs, which are characterized by the following features: (1) they are absolutistic (he termed this "masturbatory ideology"), as in for example, the belief that someone must be competent in everything he or she does; (2) there is no empirical evidence to support them, or existing evidence contradicts them; (3) they result in intense negative feelings, such as severe anxiety or depression; and (4) they lead to self-defeating actions (Ellis, 1986). All irrational beliefs can be reduced to the absolutistic evaluations of perceived events, which Ellis described as *musts*, *shoulds*, *has to's*, and *ought to's*.

He stated that people's "difficulties largely result from distorted perception and illogical thinking" and a person "can rid himself of most of his emotional or mental unhappiness . . . and disturbance if he learns to maximize his rational and minimize his irrational thinking" (Ellis, 1962, p. 36).

The idea that cognitions play a crucial role in psychological well-being was not new, as both Beck and Ellis acknowledged (A. T. Beck et al., 1979; Ellis, 1962). Ancient philosophers such as Socrates and Epictetus claimed that "people are disturbed not by things, but the views they take on them." This phenomenological approach to psychology would appear in Immanuel Kant's writings and the more contemporary work of Adler (1927), Horney (1950), and Sullivan (1953). Ellis (1962) pointed out that "self-help" systems taught by the great religious leaders such as Gautama Buddha and Jesus Christ were essentially cognitive behavioral in nature.

Another crucial historical factor contributing to the development of cognitive therapy was experimental cognitive psychology, with its mediational information-processing model of cognition, which was extended to clinical constructs (e.g., Hamilton, 1980). In the field of cognitive psychology, significant researchers include Kelly (1955), with his formulation of "personal constructs," and Richard Lazarus, who carried out studies that documenting the involvement of cognitive mediations in anxiety (Lazarus, 1966; Lazarus & Launier, 1978). As was mentioned earlier, cognitive therapies incorporate behavior interventions, and that is why most cognitive therapy proponents call their approaches cognitive behavioral; similarly most behavior therapists regard themselves as CBT therapists. Although the Association for Advancement of Behavior Therapy has not incorporated "and Cognitive" in its title, its European counterpart, the European Association for Behaviour Therapy, changed its name to the European Association for Behaviour and Cognitive Therapies in 1992.

Development of Cognitive-Behavioral Therapy

In the beginning, the cognitive concepts of Beck and Ellis were too diffuse and too cognitive for determined behaviorists, but because they respected behavior therapy and incorporated components of it into their treatment modalities, behavior therapists began to be more and more interested in this approach. Besides, the reported achievement of Beck's method in the treatment of depression was not easily undervalued. Dissatisfaction with previous models of therapy, together with findings

revealing new cognitive aspects of human functioning that were not covered under the behavior therapy umbrella, was the basis on which a number of prominent therapists and theorists began, during late 1960s and 1970s, to identify themselves as cognitive behavioral in orientation. That includes Aaron Beck (1967, 1970) and Ellis (1962), but many others as well, for example, Cautela (1967), Mahoney (1974), and Meichenbaum (1977; Meichenbaum & Cameron, 1973). Their example drew the attention of others to research on and practice of CBT. This was facilitated by the founding of a journal in 1977 called *Cognitive Therapy and Research*, which allowed researchers and clinicians to present their ideas and findings to a wide audience. Cognitive concepts have widened the exploratory power and understanding of abnormal behavior and its origin. The growing body of research studies and reviews demonstrated that cognitive-behavioral interventions have a positive clinical impact (e.g., Berman, Miller, & Massman, 1985; Shapiro & Shapiro, 1982) and strengthened the position of CBT further. The two streams of therapy, cognitive and behavioral, were particularly well fused by the development of a theoretical model and specific therapeutic intervention for panic disorder (Barlow & Cerny, 1988; Clark, 1986), regarded by many as the most effective psychological treatment ever invented.

There are many therapies that can be placed under the cognitive-behavioral umbrella. Some of the major ones are rational-emotive behavior therapy, cognitive therapy, self-instructional training, systematic rational restructuring, anxiety management training, stress inoculation training, problem-solving therapy, self-control therapy, and structural and constructivist psychotherapy.

Around the 1990s, a number of new approaches or extensions of previous CBT treatments, described as the third wave of CBT (Hayes, 2004b), appeared. They were a reaction to doubts that had arisen about some of the core assumptions of traditional CBT (Hayes, 2004a; Hayes, Leoma, Bond, Masuda, & Lillis, 2006), especially the assumption that direct cognitive change is necessary for clinical improvement. Other factors leading to the development of the third wave of CBT were new ideas in the philosophy of science and increasing awareness of the Buddhist tradition and the benefits of cultivating mindfulness meditation.

New Directions in CBT: The Third Wave of Cognitive and Behavior Therapy

In the past 20 years, a number of therapies inspired greatly by the pioneering work of Jon Kabat-Zinn's

(1990) mindfulness-based stress reduction program have been developed. The leading approaches, aside from mindfulness-based stress reduction itself, are dialectical behavior therapy (Linehan, 1993), acceptance and commitment therapy (Hayes, Strosahl, & Wilson, 1999), and mindfulness-based cognitive therapy (Segal, Williams, & Teasdale, 2002). Others include the cognitive-behavioral analysis system of psychotherapy (McCullough, 2000), functional analytic psychotherapy (Kohlenberg & Tsai, 1991), integrative behavioral couple therapy (N. S. Jacobson, Christensen, Prince, Cordova, & Eldridge, 2000), Roemer and Orsillo's (2002) treatment of generalized anxiety disorder, and mindfulness-based eating awareness training (Kristeller & Hallett, 1999). As Hayes (2004b) described,

Grounded in an empirical, principle-focused approach, the third wave of behavioral and cognitive therapy is particularly sensitive to the context and functions of psychological phenomena, not just their form, and thus tends to emphasize contextual and experiential change strategies in addition to more direct and didactic ones. These treatments tend to seek the construction of broad, flexible, and effective repertoires over an eliminative approach to narrowly defined problems, and to emphasize the relevance of the issues they examine for clinicians as well as clients. The third wave reformulates and synthesizes previous generations of behavioral and cognitive therapy and carries them forward into questions, issues, and domains previously addressed primarily by other traditions, in hopes of improving both understanding and outcomes. (p. 658; italics in original)

Proponents of these approaches claim that the heart of traditional CBT, that is, challenging dysfunctional beliefs through rational, logical analysis, is not necessary (Hayes, Follette, & Linehan, 2004). Instead of primarily focusing on challenging the validity of thoughts, therapy should lead to a direct modification of cognitive processes, particularly attention (Orsillo, Roemer, & Hollowka, 2005). There is growing awareness, which has been labeled a "second cognitive revolution," that our thoughts, emotions, and behavior are to a great extent the consequence of unconscious processes (Westen, 2000). In this regard, the new wave of behavioral therapies seems to offer access to automatic and dysfunctional processes, which can be achieved through the cultivation of mindfulness and acceptance. The key element of mindfulness- and acceptance-based psychotherapy is helping the patient make a shift from a judgmental and controlling stance toward internal experiences to a more compassionate and accepting one (Orsillo et al., 2005). Critics of traditional content-focused CBT, with its em-

phasis on symptom control and management, have pointed out that such an attitude might strengthen the individual's striving to get rid of unwanted and unpleasant experiences like anxiety or obsessions. Attempts to change the form or frequency of internal events (e.g., thoughts, emotions, memories, images, physiological sensations), called experiential avoidance (Hayes, Wilson, Gifford, Follette, & Strosahl, 1996), are usually not alleviated but rather contribute to the development and maintenance of many forms of psychopathology (Hayes et al., 1996; Stewart, Zvolensky, & Eifert, 2002). Third-wave CBT therapies incorporate strategies to help change the patient's relationship with his or her particular form of suffering, to decrease internal struggle, and to normalize unpleasant experiences. Most importantly, they switch the emphasis from "think and feel better" to "live better." Here, the goal for therapy is to reorient the patient from trying to change his or her thoughts and feelings to making positive behavioral change—encouraging the patient to meaningfully engage in life in accordance with his or her values and goals, in spite of his or her suffering. To achieve this, mindfulness meditation, with its qualities of acceptance, non-striving, decentering, and letting go, is a main strategy. Mindfulness-based interventions use different methods to teach mindfulness awareness. In a formal meditation practice, participants usually sit for a period of time with a straight back, focusing on a specific stimulus, such as the breath (single-object awareness). They are instructed to redirect their attention to that object whenever their minds wander or to observe nonjudgmentally the constantly changing stream of stimuli (choiceless awareness) as they arise and pass. Informal practices involve various exercises of mindfulness in daily life activities, such as eating, walking, and breathing, in which a person is instructed to carefully observe whatever occurs, with no attempt to evaluate or get rid of it, but instead to simply note it and let it go. Mindfulness-based stress reduction and mindfulness-based cognitive therapy use both formal and informal practice, whereas acceptance and commitment therapy and dialectical behavior therapy emphasize shorter and less formal activities (Baer & Krietemeyer, 2006). Readers interested more in the third wave of CBT are referred to more extended reviews and books (e.g., Baer, 2006; Hayes et al., 2004).

The third wave of CBT has recently received much attention and interest from medical and psychotherapeutic societies but has also been met by criticism and rejection. Hofmann and Asmundson (2008) have argued that the founders of acceptance and commitment therapy misunderstand key concepts of CBT, leading to their criticism CBT, and that their proclamation of the need for

a new approach was based on their poor understanding of these concepts. According to Corrigan (2001), third-wave therapies are "getting ahead of the data" (p. 192) and are far from the principles of empirical validation laid down by the first-wave behavior therapists. Third-wave therapies share some common features but differ significantly, for example, in the extent to which they subscribe to behavioral analysis or radical behaviorism. Öst (2008) recently reviewed the efficacy of third-wave CBT treatments by conducting a meta-analysis of 29 RCTs (13 RCTs in acceptance and commitment therapy, 13 in dialectical behavior therapy, 1 in cognitive behavioral analysis system of psychotherapy, and 2 in integrative behavioral couple therapy). He concluded that the main/mean effect size was moderate for both acceptance and commitment therapy and dialectical behavior therapy, but that none of the third-wave therapies fulfilled the criteria for empirically supported treatments.

DEFINING COGNITIVE-BEHAVIORAL THERAPY

According to Clark (1995), "At the very heart of the cognitive therapy model is the view that the human mind is not a passive receptacle of environmental and biological influences and sensations, but rather that individuals are actively involved in construing their reality" (p. 156). The label of cognitive behavioral has been proposed for all approaches that reject the idea that behavior is determined primarily internally, as with Freud, or primarily externally, as with Skinner, and apply approaches that seek to integrate both views (Meichenbaum, 1977).

CBT can be viewed as a family of models that share fundamental theoretical assumptions and usually are similar to the referral exemplar of CBT—Beck's standard cognitive therapy for depression.

The relative emphasis on cognition and behavior varies among cognitive-behavioral approaches; however, Dobson and Dozois (2001) proposed that three main propositions are shared by all forms of CBT:

- (1) Cognitive processes affect behavior.
- (2) Cognitive activity can be monitored and changed.
- (3) Changes in people's cognitions—thoughts, interpretations, and assumptions—can lead to modification in their actions.

Cognitive theory and therapy consider cognitions the key to psychological disorders. Cognition is defined

as a function that involves inferences about one's experiences and about the occurrence and control of future events (Alford & Beck, 1997). Beck discovered that rigid, automatized forms of thinking form the basis for the clinical manifestation of emotional problems. As a great amount of research demonstrates, cognitive processes are implicated in many forms of psychopathology (Dobson & Kendall, 1993), and modification of these maladaptive patterns of thinking can ameliorate these psychopathological states.

The three propositions listed by Dobson and Dozois (2001) as fundamental to the CBT model do not preclude other important assumptions that might be added. According to Freeman and Reinecke (1995), CBT models assume that the processing of information is active and adaptive and that it allows individuals to derive a sense of meaning from their experience. Although CBT models assert that the system of beliefs of each individual is idiosyncratic, clinical disorders can be distinguished on the basis of specific cognitions (cognitive content and products) common to patients suffering from the same disorder. The nature of the patient-therapist relationship and the typical structure of therapeutic process are shared by different cognitive-behavioral therapies. Beck (1979) defined CBT as "an active, directive, time-limited, structured approach used to treat a variety of psychiatric disorders" (p. 3). "Active" refers to the fact that most forms of CBT are either implicitly or explicitly educative in nature. One of the often mentioned characteristics is the specific problem-focused nature of cognitive-behavioral interventions. This orientation on problems partially explains the usual time limits of this therapy; most of the CBT treatment manuals describe a treatment consisting of 12–16 sessions (Chambless et al., 1996). The time-limited nature of CBT distinguishes this form of therapy from psychoanalytic therapy, which is usually long term. What must be stressed, however, is that CBTs cannot be defined by their techniques or strategies to promote change (Clark, Beck, & Alford, 1999). Any intervention that brings about cognitive change as a means of facilitating emotional and behavioral change, and any model that explicitly acknowledges the mediating or moderating role of cognition in human functioning, might be considered a variant of CBT. Acknowledging the key role of cognition in the theory of psychopathology and therapeutic change doesn't mean that CBTs reject the role of non-cognitive factors in vulnerability and the treatment of psychiatric disorders. Cognitive-behavioral models assert that human mental health and psychopathology are multiply determined. This is consistent with contemporary research in developmental psychopathology,

which indicates that biological, environmental, social, personality, and cognitive factors interact in contributing to individual pattern of psychopathology. There is a strong emphasis on both theory and therapy in CBT to be empirically validated.

As Reinecke and Clark (2004) have stated, "Much of the current appeal of CBT stems from three factors—its intuitive simplicity, its reliance upon empirical methods for testing validity of its models and effectiveness of its treatments, and its clinical utility" (p. 2). In fact, partially because of these characteristics, it has been reasoned that cognitive theory constitutes a unifying theory for psychotherapy and psychopathology (Alford & Beck, 1997; Alford & Norcross, 1991).

THE ANATOMY OF THE THERAPEUTIC ACT

Clinical Assessment and Diagnosis

Traditionally, behavior therapy started with a functional analysis of the problematic behavior that was the target of the intervention. A behavioral intervention is always preceded by a detailed analysis of the factors that have generated and maintained a certain (dysfunctional) behavior. Functional analysis is sometimes known as a case formulation.

Behavior therapists have been reluctant to use diagnostic systems based on a syndrome approach to dysfunctional behavior, such as the *Diagnostic and Statistical Manual* of the American Psychiatric Association (1994). To this day, leaders of behavior therapy (Hayes, 1997) question the utility of psychiatric diagnoses in psychotherapy. Behavior therapists contend that ultimately what matters is the behavior that is to be modified.

Regardless of whether this is good idea or not, most cognitive-behavioral interventions are targeted to a disorder that is defined by the *DSM* categorical system. Cognitive-behavioral psychopathological models have a lot of valid points against the *DSM-IV*, but the dominant stance is that if research were conducted under diagnostic criteria other than the *DSM*'s, it would be very difficult to compare outcome data for various interventions (e.g., medication). It was perhaps for this reason that the Beck Depression Inventory (A. T. Beck, Steer, & Brown, 1996) was modified so that it would be compatible with the *DSM*'s construct of major depression.

So, for the last two decades, most outcome studies and interventions have been targeted at mental disorders as defined by the most recent version of the *DSM*.

Given the commitment of cognitive-behavioral therapy to empirical research, cognitive-behavioral therapists are expected to choose interventions whose efficacy has been empirically evaluated. Since most of this research is targeted to *DSM*-defined disorders, the first step in the assessment phase of CBT is identifying any mental disorders.

DSM categories are meta-theoretical or descriptive so that they are presented in language that is acceptable to mental health professionals of all theoretical backgrounds. Although the multiaxial diagnostic approach provides a lot more information than older forms of diagnosis, the fact remains that a *DSM* diagnosis does not provide all the information needed to for a psychotherapeutic intervention. No matter how carefully the intervention is conducted, a *DSM-IV* diagnosis does not tell us how capable the client is of engaging in a good therapeutic alliance or how much sense the cognitive approach makes to this person.

Because *DSM-IV* categories are meta-theoretical, a second step in assessment is necessary to provide us with the necessary information to conduct cognitive-behavioral therapy. This is normally known as a case conceptualization or case formulation.

Clinical Case Conceptualization

Jacqueline Persons defines a case conceptualization as a series of hypotheses that establish a relationship between the different problems that afflict a given patient, postulating the psychological mechanisms that may have participated in the predisposition, triggering and maintenance of these problems (Persons & Davidson, 2001). Clearly, a conceptualization is driven by a certain psychopathological theory. It is, in fact, an ideographic theory about a patient that is based on a general—nomothetic—theory (Persons & Davidson, 2001). Based on a certain cognitive theory, the formulation must provide an answer to the following question: What beliefs were activated by which triggering factors, generating what dysfunctional thoughts, moods, and behaviors?

A young woman comes to consultation complaining of bouts of high anxiety (panic attacks), which she began to experience one night at a nightclub. She had just drunk an energy drink and smoked marijuana. She suddenly experienced some unusual sensations (autonomic activation) that she could not explain and that made her feel vulnerable. She felt very anxious and subsequently stopped clubbing in order to avoid experiencing those sensations again. A cognitive-behavioral conceptualization of this experience would say that the unusual sensations (the trigger) were interpreted as

threatening by the activation of the belief “I am vulnerable.” The activation of the belief led to the negative automatic thought “There is something physically wrong with me!” As this crossed her mind, she felt marked anxiety (the emotion). She became so afraid that she decided to stop going to this club (avoidant behavior). She thought that doing this prevented the negative affect from occurring again (avoidance as a safety measure).

Case conceptualizations are important because most outcome (efficacy) studies are conducted on relatively “pure” patients (without significant comorbidity), under relatively “ideal” conditions. Until we have many more outcome studies that look at effectiveness, we will need conceptualization-driven treatments for clients with comorbid conditions or other complexities that represent the everyday challenges of psychotherapists.

Treatments based on case conceptualizations do not oppose but complement treatments based on empirical evidence. Case conceptualization guides us in conducting evidence-based treatments by providing a framework for understanding how the disorder manifests itself in a particular individual. The main reason for case conceptualization is its clinical utility. It aims at planning effective interventions, including the identification and reversion of impasses and flops.

There are many different models of case conceptualizations (J. S. Beck, 1995; Persons & Davidson, 2001), but they normally include some basic elements. These are a diagnosis, a list of the present problems, a working hypothesis about the relationship between the present problems and the cognitive profile of the client, and a treatment plan that outlines not only the deficits but the strengths and advantages of the client. In order to precisely diagnose an anxiety disorder, for example, it is important to pay attention not only to the nature of autonomic nervous system activation, but also to what is feared by the patient (i.e., the threatening appraisal). Fear of flying (a specific phobia) is frequently confused with fear of being inside a flying plane (agoraphobia). Cognitions about threat (the threatening appraisal) are central to CBT, since treatments are specific to a certain set of cognitions.

Thus, all problems mentioned by the patient (not only those pertaining to the disorder) must be described in cognitive, emotional, and behavioral terms. CBT therapists socialize the model to the patient as it is generated. Graphs, metaphors, and bibliotherapy are commonly used to this end. For example, a panic patient may be told that “As you felt that unexpected sensation, you said to yourself, ‘I am having a heart attack.’ This threatening thought triggered your anxiety, leading you

to rush to the emergency room.” As in other forms of psychotherapy, in order to generate a complete list, it is useful to probe all the different areas of the patient’s life: psychological and psychiatric issues, physical health, interpersonal issues, work or academic issues, finances, housing, cultural and religious issues, and leisure, as well as issues that patients may avoid: substance abuse, suicide ideation or attempt, rituals, and impulsive behavior.

Therapists must assign a score to each problem, according to intensity, frequency or degree of interference. With complex patients, the first targets for treatment are life-threatening behaviors and behaviors that interfere with treatment.

Therapists may observe problematic issues that are not perceived as such by the patient. This should be considered first and eventually addressed when informed consent is obtained. Also, parents of children and adolescents may observe problems that are not perceived as such by the child or the adolescent.

The working hypothesis is the core of the case conceptualization. It must identify cognitive structures (core beliefs, intermediate beliefs, and automatic thoughts), the events and situations that trigger these beliefs, and a clinical theory of their potential origins. In sum, it must generate hypotheses that link the problems listed with the beliefs, precipitants, and origins (J.S. Beck, 1995; Persons & Davidson, 2001). The therapist usually identifies automatic thoughts by asking the patient to focus on what he or she thinks when experiencing the unpleasant emotions that drove him or her to therapy (A.T. Beck et al., 1979). Intermediate beliefs are rules and attitudes derived from core beliefs and represent ways to cope with them. Therapists can identify core beliefs (Leahy & Holland, 2000; Padesky & Greenberger, 1995) and intermediate beliefs by several means, for example, by looking at the first part of an assumption (if . . . , then . . .), by looking at common themes in the patient’s automatic thoughts, or by using a belief questionnaire, such as the Dysfunctional Attitude Scale (Weissman & Beck, 1995).

The treatment plan includes the objectives of the therapy, its modality and frequency, the type of interventions to be used, any adjunct therapies, and the potential obstacles that may arise. Cognitive therapists are expected to avoid the traditional tendency to focus on deficits and pay equal attention to the client’s strengths and advantages, drawing upon them to generate adequate treatment strategies. For example, one of the strengths of the patient with panic mentioned before was her comfort experiencing emotions and discussing them in therapy.

The Therapeutic Relationship

The quality of the therapeutic alliance is the most powerful predictor of success in psychotherapy (Howarth & Symonds, 1991; Safran & Segal, 1990). The alliance involves not only the nature of the therapist-patient relationship, but also an agreement on their respective roles and on the goals for the therapeutic undertaking.

What is about the nature of the therapeutic relationship in CBT? In Beck’s cognitive therapy (A.T. Beck et al., 1979), the relationship is characterized by collaborative empiricism. Patient and therapist accept that thoughts are just mental events, mere representations of reality. Clients learn to treat their thoughts and beliefs as hypotheses, not as self-evident truths (distancing). As in science, these hypotheses must be tested against the data provided by the environment (questioning of cognitive content). This is a collaborative endeavor in which the patient has to learn how to become his or her own therapist (i.e., he or she has to learn new ways of relating to his or her internal experience). This must be achieved in the spirit of guided discovery. Being accurately empathetic, the cognitive therapist selects experiences that will allow the patient to acquire new perspectives on old problems in a gradual way. Highly inspired by Socratic dialogue, the patient’s learning is mostly experiential.

Cognitive therapists strive to generate cognitive dissonance, thus favoring the chances of psychological change. If the client discovers that belief A is contradicts belief B (or contradicts the data), then he or she will be highly motivated to find a dialectical alternative, belief C. The main obstacle to change is rigidity; the therapeutic relationship must encourage, teach, and foster psychological flexibility.

COGNITIVE AND BEHAVIORAL INTERVENTION TECHNIQUES

As we have already mentioned, the acronym CBT is used as a generic denomination for the many forms of therapy in the cognitive-behavioral paradigm. Despite their many and considerable differences, Beck’s cognitive therapy, Ellis’s rational-emotive behavioral therapy, Linehan’s dialectical behavior therapy, Wells’s metacognitive therapy, and Hayes’s acceptance and commitment therapy, to name but a few, are all considered part of the CBT family. Therefore, it is not easy to provide a summary of CBT interventions that can do justice to the all their approaches, goals, and methodology. What

follows is an honest attempt to give the reader an idea of what the core of CBT is.

Every cognitive-behavioral treatment is based on a psychopathological model that provides the rationale for the selection of interventions and the sequence in which they are to be applied. CBT is based on the premise that cognition, emotion, and overt behavior are interdependent subsystems. Thus, the modulation of any subsystem will inevitably lead to changes in the other two. Therefore, there are no “pure” cognitive or behavioral interventions. If you ask your client to behave differently in an experimental situation, chances are that his or her way of thinking (cognition) about that situation will change. Conversely, if you challenge the rationale of a certain behavior, chances are that your client will start doing things differently. So, exploring new behaviors is a powerful way of changing cognition and, conversely, changing cognition may be the best way of modifying behavior.

If you provide a bulimic patient with psychoeducation about the link between strict dieting, bingeing, and gaining weight, chances are that he or she will give up that pattern of eating (change in behavior) and stop blaming him- or herself for being “too weak” to stay on a diet (change in cognition) and feeling guilty about it (change in emotion). A healthier eating behavior will result in the regulation of negative affect (change in emotion) and a greater sense of self-control (change in cognition).

CBT acknowledges the technical contributions of several models of psychotherapy. The technical eclecticism of CBT does not mean, however, that techniques are employed for the same ends for which they were initially devised.

Some Basic Technical Principles

Because behavior is to a great degree voluntary, all cognitive-behavioral treatments begin with attempts at modifying behavior. Some theoreticians (Hayes et al., 1999) argue that there is no other way, since internal experience (thoughts and emotions) is not directly manipulable.

Our psychopathological model identifies the behaviors that serve as maintaining factors for the targeted disorder (e.g., avoidance and safety behaviors in anxiety disorders, passive and asocial behavior in depression, strict dieting in bulimia nervosa, use of substances as a means of regulating negative affect in addictions). The client is given an explanation about the role of that behavior in maintaining the problem (the therapist’s conceptualization is shared with the client) and is instructed in how to modify this behavior. This is of

crucial importance because these behaviors are all too often dysfunctional strategies used by the client to deal with the problem (such as anxious or depressive symptoms, binges, addictive behaviors).

Graded task assignment is one of the principles of behavior change. Although drastic modification of behavior is sometimes used (e.g., “flooding”—massive *in vivo* exposure—in the treatment of specific phobias), gradual change (exposure) guided by the hierarchy of anxiogenic stimuli is the most common option. Behavior modification is not governed by social expectations, but by an experimental attitude. The client is asked to behave in new ways and to observe his or her emotions and cognitions as the new experience evolves.

As clients begin to change their usual patterns of behavior, the therapist begins to apply a number of strategies aimed at making cognition flexible. This is generally known as cognitive restructuring. In contemporary CBT there is some debate about what the essential component of this strategy is.

Beck’s cognitive therapy for depression (A. T. Beck et al., 1979) gave a central role to cognitive restructuring. His theory postulated that distorted negative thinking is an essential part of depression, and so cognitive modification is mostly about challenging distorted cognitive content and replacing it with unbiased, data-driven cognitions. Other cognitive theorists and therapists have (Segal et al., 2002) posited that cognitive therapy works not so much because it changes faulty cognitive content, but rather because it helps clients contemplate their negative thoughts as mere mental events, thus helping them to distance or decenter from them, and reducing the negative emotional impact. Of course, this is implicit in Beck’s therapy, because the client is asked to view his or her thoughts as hypotheses to be tested rather than reflections of reality, but early cognitive therapy put too much of an emphasis on rationality and tended to view the impact of cognition on mood as a one-way process.

But clients rarely go to therapy because they want to change their thoughts; they normally go because they want to get rid of unpleasant sensations, feelings, or emotions.

So how does CBT deal with emotional change? Despite the emphasis it puts on cognition, we must stress that CBT cannot be performed successfully unless central consideration is given to emotions. When cognition or behavior is modulated, success is often evaluated in terms of the positive impact on emotions.

But emotions can also be the direct target of an intervention. One of the cornerstones of CBT, emotion-processing theory (Foa & Kozak, 1986), indicates that

emotions cannot be modified unless activated. Avoidance of “negative” emotions is a typical strategy used by patients with anxiety or mood disorders. Their unwillingness (Hayes et al., 1999) to experience certain emotions prevents the processing of those emotions, thus maintaining the reasons for continued avoidance. This is, for example, the dilemma of people affected by post-traumatic stress disorder.

Emotions are not negative per se; this is more a by-product of our appraisal of them. A person with panic disorder, for example, may be terrified at the idea of experiencing a racing heart, a sense of danger, or heavy breathing. But every day thousands of people pay good money and stand in line for a long time at Disney World for the privilege of riding a roller coaster, eagerly waiting to feel a pounding heart, a sense of danger, muscle tension.

So CBT encourages acceptance of and exposure to “negative” emotions. It challenges a problematic belief that is common among clients: “I will change first (by just talking in therapy), and then I will confront my emotions.” People with social anxiety disorder, for instance, frequently come to therapy with the expectation of finding the “cause” of their anxiety, removing it, and then happily proceeding to face the challenges of interpersonal interaction. Psychotherapy can thus become a sophisticated—and expensive—safety measure.

Metaphorically, we can tell our clients that in order to mold steel, we need to heat it up. It may not be pleasant and may take a lot of energy, but it allows us to turn a very rigid metal into a plastic substance that we can shape at will.

Behavioral Techniques

CBT uses all the armamentarium developed by the rich tradition of behavior therapy. A detailed explanation of all these techniques is well beyond the scope of this chapter, but we will provide a synthesis of some of the most characteristic interventions. The reader is reminded that these interventions may be used in different treatment packages to serve different purposes; therefore it is important to pay attention not only to their form but also to their function in each protocol.

Exposure

The essence of exposure is bringing patients into contact with the cues that evoke their negative emotions, in a deliberate, self-controlled manner. They remain in contact with these cues until (1) their anxiety diminishes (habituation), and (2) they begin to realize that

the consequences they expected do not occur (disconfirmation). The types of cues that become the target of the technique are decided in terms of the case conceptualization. A person who fears cockroaches can be exposed to a vivid image or a video of a cockroach, and eventually to the real insect. A person with panic disorder can be exposed to the internal sensations that he or she fears (interoceptive exposure).

Types of exposure. Traditionally, exposure was conducted in vivo or imaginally. When patients come into contact with cues in real-life situations, we call it in-vivo exposure; when they come into contact with cues in their imagination, we call it imaginal exposure. With the advent of online video and virtual reality, there is a now a middle ground between the two classical options, which provides an intriguing opportunity to expand exposure in a safe environment for the client. Although in-vivo exposure is normally preferred, imaginal exposure is necessary when one is dealing with feared thoughts, memories, or internal cues.

Conducting exposure. The therapist begins by explaining the rationale for the procedure to the patient and discussing its advantages and disadvantages and clients’ usual concerns. Most patients learn to do exposure assignments on their own in an effective manner. Some patients, however, initially need the assistance of the therapist. Gradual exposure is more commonly used than massive exposure. A hierarchy of feared stimuli must be established collaboratively with the patient in order to ensure a graded approach. Going from imaginal exposure to in-vivo exposure is one way of implementing a gradual approach. The client repeats the procedure a number of times, experiencing a decline in the intensity of the negative emotion elicited each time.

Graded Task Assignment

This strategy may be used when a patient feels too depressed and hopeless or too anxious to begin a complex or demanding task (A. T. Beck et al., 1979). A complex action is broken into smaller components, and the client is asked to attempt these steps in a sequence. This strategy is useful for tackling maladaptive perfectionism and performance anxiety and for challenging hopelessness. It is usually applied at the beginning of the session, and then the client is expected to continue the sequence of tasks as part of his or her homework.

Modeling

Based on the principles of observational learning (Bandura, 1977a, 1977b), this strategy aims at helping cli-

ents find adequate models for the behavior that they want to acquire. This can be performed by the therapist, if necessary, but models are often found in films and in the client's circle of friends, workmates, or schoolmates. Modeling is commonly used for skills training and exposure exercises. It must be faded out as soon as possible, so that the client increases his or her sense of self-efficacy.

Problem-Solving

Lack of problem-solving skills is observable in patients with severe mental disorders such as major depression or substance dependence, who resort to dysfunctional behaviors when facing life challenges as a result of their lack of ability to engage in more functional alternatives. The stages of problem solving can be summarized as (1) defining the problem, (2) setting goals, (3) brainstorming solutions, (4) evaluating possible solutions, (5) selecting a solution, (6) identifying steps for implementing the solution, (7) cognitively rehearsing the solution, (8) implementing the solution, and (9) evaluating the outcome. Traditional behavior therapy focused primarily on problem solving, but researchers (Linehan, 1993) have indicated that this first-order change strategy can be problematic when applied initially to clients with complex and severe mental disorders.

Social Skills Training

The aim of this strategy is to help the patient improve or develop skills involved in meeting other people, carrying on conversations, acting appropriately in social situations, and initiating relationships. The first step involves assessing the client's deficits. Some clients need to develop basic skills, while others just need to get rid of the inhibition caused by anxiety. The second step, modeling, can be performed by the therapist or observed in real life or in films. When this is completed, therapist and patient role-play the skills. Finally, the patient performs the skills in real-life situations.

Relaxation

Progressive muscle relaxation (PMR) and its variations is the most commonly used relaxation strategy in CBT. Developed by E. Jacobson (1938), it teaches the patient a series of exercises that become progressively shorter and that are designed to condition a relaxed response that can ultimately be evoked in a very short amount of time (normally as the anxiety-provoking situation takes place). Although effective, it takes a considerable

amount of time to train someone in PMR, so it is often replaced by training in breathing relaxation, which is less time consuming. Training in PMR begins with a rationale for the intervention. PMR is presented as a skill for counteracting the physiological responses to anxiety that concern the patient the most. As a coping skill, it must be practiced in order for the patient to gain mastery.

Barlow and Cerny (1988), Öst (1987), and Clark (1989) suggest a sequence of exercises in which the patient tenses a group of muscles and then abruptly releases the tension, breathing calmly and saying, "Relax!" to him- or herself, thus experiencing that muscle group in a more relaxed state. The steps, reflecting increased skill and shortened time, are:

- (1) Twelve-muscle-group relaxation (lower and upper arms, lower and upper legs, thighs, stomach, upper chest and back, shoulders, back of the neck, lips, eyes, eyebrows, upper forehead, and scalp)
- (2) Eight-muscle-group relaxation (entire arms, entire legs, stomach, upper chest and back, shoulders, back of the neck, face, forehead, and scalp)
- (3) Four-muscle-group relaxation (entire arms, upper chest and back, shoulders and neck, face)
- (4) Release-only relaxation (same four groups, but without using initial tension)
- (5) Cue-controlled relaxation (the patient takes three deep breaths and thinks, "Relax," with each exhalation, while scanning the body for any tension and releasing it; the word "relax" becomes the cue signaling the client's body to relax)

The patient practices these skills daily and progressively applies them when he or she detects early warning signs of anxiety.

Breathing Relaxation

Patients are sometimes used to breathing only into their upper chests, sucking their abdomens in as they breathe, which leads to hyperventilation or other breathing difficulties. In diaphragmatic breathing, the diaphragm, at the base of the lungs, is distended, pushing the abdomen out and drawing air into the lower lungs. Once patients have mastered this skill, they are taught to breathe slowly, holding the breath for 4 seconds, and then gently letting the air out of their lungs, usually at least a half second longer than it took them to breathe in. The idea is for the patient to breathe rhythmically like this for a couple of minutes and become aware of the associated relaxation. Holding on to the breath is

also one of the cornerstones of mindfulness practice and is a skill that is used to steady the mind (Hayes, 2004a).

Visualisation

Visualization combines elements of relaxation and attentional training. Patients are asked to imagine themselves in a place or situation they find pleasant and relaxing (real or just imagined). The more vivid the image becomes, the greater the impact on emotions and physiological response (e.g., muscle tension) is. Patients increase the vividness of the image by focusing their attention on visual, olfactory, or acoustic stimuli.

Behavioral Activation

Traditionally used in the treatment of depression, the global goal of behavioral activation (reward planning and activity scheduling) is to increase behaviors that likely lead a patient to be rewarded in some way. Increasing pleasurable activities helps lift a person's mood and also helps decrease rumination (A.T. Beck et al., 1979). It also is helpful in dealing with procrastination and behavioral avoidance.

Behavioral activation consists of four steps: (1) monitoring current activities in terms of mastery and pleasure, (2) developing a list of rewarding activities, (3) planning the activities, and (4) engaging in the activities. Carrying out these tasks usually triggers dysfunctional cognitions. Clients often assume that they should wait until they want to do something, and they are surprised to find that engaging in the activities actually increases their motivation to perform them. Also, contrary to their predictions, they normally derive a certain amount of pleasure from the activities, even from those that demand plenty of energy. Behavioral activation offers many opportunities for challenging clients' learned helplessness and hopelessness.

Cognitive Strategies

Clients must learn about the role of cognition in originating and maintaining mental disorders so that they can understand the rationale behind the use of cognitive techniques. The main objective of cognitive strategies is to increase cognitive flexibility. Clients must learn that we relate to the world by means of thoughts, but that these thoughts are just mental events that do not necessarily reflect the exact nature of reality. This is a metacognitive ability (being able to think about our

own thoughts) that may be impaired in severe mental disorders.

Clients are helped to gain better awareness of their thoughts, rules, attitudes, and beliefs. This is a preliminary step in challenging cognitions, but also in distancing from them in mere contemplation. Very much like in *Casablanca*, where "a kiss is just a kiss," a thought is just a thought, a mere mental event, in cognitive therapy.

Psychoeducation

Psychoeducation originated in medical practice when the clinical advantages of fully informing patients about their conditions became evident. Psychoeducation serves yet another purpose in CBT. As we mentioned before, most CBT approaches are based on the information-processing paradigm. From this perspective, it is clear that the kinds of hypotheses that we can generate depend on the information available. It is common for human beings to suffer because of mistaken beliefs. Bulimic patients, for example, try to control their binges by making their diets increasingly strict, ignoring the fact that binges are the natural consequence of this kind of dieting. Panic patients commonly fear physical exercise or strong emotions because they believe that they can be dangerous to their cardiac functioning.

Therefore, in CBT, psychoeducation also serves the purpose of giving the patient correct and factual information, which may be indispensable for generating alternative functional views of certain experiences.

Socializing the Cognitive Model

Our conceptualization is shared with the client, so that he or she will understand the importance of cognitive factors in the targeted disorder. Patients are educated about the importance of beliefs, automatic thoughts, cognitive biases, and the like, so that they can see the importance of paying attention to their cognition as one means of modifying the present problem. The basic rule here is that the client should understand that it is not facts that affect us, not matter how important they are, but rather the meaning we ascribe to them (A.T. Beck et al., 1979).

Bibliotherapy

At the beginning of treatment, cognitive-behavioral therapists give their clients plenty of information about the disorder from which they suffer and about the way CBT conceptualizes it. They also suggest readings that offer additional information on these topics. This has a

series of advantages. First, clients are often anxious at the beginning of therapy, and this interferes with their ability to remember the information they are given. Books and Web sites can always be used for reference, especially when the therapist is not available. Second, asking the patient to read something between sessions is a simple homework assignment that will allow the psychotherapist to assess the willingness of the patient to complete assignments. Third, the patient can read (or reread) difficult parts and ask the therapist about them in session.

This was quite a new idea in the 1970s, but with the advent of the Internet, it has become quite common for clients to access information on disorders and therapies. This information is not always accurate or may be difficult to interpret because it is not targeted to CBT clients. Suggested readings have to be accurate, up to date, and written in a simple language.

Some of the texts penned by reputed cognitive-behavior therapists have become best sellers, as in the case of David Burns's (1980) *Feeling Good*. Not only do these books provide information on the disorder, but they also offer self-help tools that can be very powerful when a therapist is not available or when the condition is mild. Fairburn's (1995) *Overcoming Binge Eating*, for example, details a self-treatment program in addition to offering a wealth of information on healthy eating habits to counter the dysfunctional beliefs of people with eating disorders. Padesky and Greenberger's (1995) *Mind Over Mood* is a very good book for those doing CBT, both therapists and clients. Aaron Beck's (1988) *Love Is Never Enough* is a great tool for working with couples in psychotherapy. All these books follow the spirit of CBT, the main goal of which is training the client to become his or her own therapist.

Monitoring

Clients are encouraged to monitor their cognitions, paying special attention to what goes through their minds at the moments when they experience the unpleasant emotions that bring them to consultation. Adequate monitoring and registration of "hot" thoughts, beliefs, or images are essential and must take place prior to any attempt to challenge these cognitions.

Questioning Cognitions

Once patients become competent at monitoring cognitions and understand their connection with the experienced mood, they are encouraged to evaluate these thoughts. Clients are encouraged to treat their cognitions

as hypotheses, not as realities. The cognitive content of dysfunctional cognitions can be accessed through a sequence of questions, as described by J. S. Beck (1995):

- (1) What is the evidence?
What is the evidence that supports the idea?
What is the evidence against this idea?
- (2) Is there an alternative explanation?
- (3) What is the worst that could happen? Could I live through it?
What is the best that could happen?
What is the most realistic outcome?
- (4) What is the effect of my believing the automatic thought?
What could be the effect of changing my thinking?
- (5) What should I do about it?
- (6) What would I tell a friend if he or she were in the same situation?

Thoughts can also be questioned in terms of their utility (i.e., what is the advantage or disadvantage of thinking like this?). Questioning the utility of a thought implies the ability to distance from the thought.

Daily Thought Record

Another way of teaching the patient to question his or her thoughts is using the daily thought record. There are many varieties of the daily thought record, but basically it has a number of columns in which clients write down the context of a situation, the mood experienced, the cognitions that were activated, and the meaning of those cognitions, as well as the evidence for and against those cognitions. Once this has been completed, clients must generate an alternative, balanced cognition that may account for all the collected evidence. One of my patients once wrote down, "Medication is not working," with the associated low mood and hopelessness. In another situation, before a meeting with his psychiatrist, he wrote down, "I am afraid he might discontinue my medication," with the associated mood of anxiety. The alternative thought was "Although medication is not working as well as I expected, I must admit that it helps a bit."

Identifying Cognitive Distortions

Aaron Beck (1967) posited that abnormal cognition is the result of distorted thinking (see also A. T. Beck et al., 1979). Identifying and challenging these distortions is

central to cognitive therapy. There is a lot of debate as to whether it is correct to use the term “distortion,” but in any case, it is clear that people with mental disorders have specific biases in their perceptions of reality.

Beck’s cognitive therapy of depression involves identifying and challenging some common cognitive distortions in depressed patients. The following is a list of the distortions described by Beck et al. (1979).

- (1) *Arbitrary inference*: The client reaches a conclusion in the absence of data or against data.
- (2) *Selective abstraction*: The client selects a negative aspect of a situation and uses it as the only piece of data for a global negative conclusion.
- (3) *Overgeneralisation*: The client makes a general rule out of an isolated negative event.
- (4) *Mind-reading*: The client “reads” negative impressions about him- or herself in the eyes of someone else.
- (5) *Fortune-telling*: The client treats a negative prediction as fact.
- (6) *Minimization, maximization*: The client minimizes positive data and maximizes negative data in order to maintain his or her hypothesis.
- (7) *Personalization*: The client attributes to him- or herself some negative outcome without justification.
- (8) *Catastrophic thinking*: The client believes the worst outcome is the only one possible.
- (9) *All-or-none thinking*: The client views a situation in extremes.

Socratic Dialogue

This old dialectical skill became one the central techniques of cognitive therapy at its inception in the 1960s. Socratic dialogue is very useful when patients rigidly hold on to certain beliefs, enabling the therapist to generate cognitive dissonance without causing too much tension in the therapeutic relationship. The therapist, because of his or her knowledge of psychopathology, knows in advance where the false premise or contradiction of the client’s argument lies. He or she formulates questions aimed at detecting that contradiction, thus generating dissonance in the client’s view of the matter. Perception of argumentative incongruence is a powerful tool for psychological change.

The Downward Arrow Technique (Vertical Descent)

This is a common technique for detecting core beliefs. The therapist enounces the patient’s thought and then

asks, “And this means . . . ?” encouraging the client to identify the implied meaning of the thought. If a patient thinks, “I will fail this exam,” the implied meaning may be “I am academically incompetent.” If a patient thinks, “I cannot stand strong emotions,” the implied meaning may be “I am vulnerable.” Core beliefs are not deep cognitions, although some authors use the depth metaphor. Core beliefs are best viewed as the general rule that generates the specific case determined by the situation. Their identification is more difficult than that of automatic thoughts because they commonly implicit, rather than explicit.

Cognitive Continuum

Continua ratings are commonly used to challenge extreme, all-or-nothing forms of thinking. If a client says, “This is the worst thing that could happen,” the therapist asks him or her to think of the best possible outcome, then to reflect on the really worst possible outcome and then to try to place the experience on the continuum.

Pie Charts

Pie charts are a helpful reattribution technique commonly used to challenge ideas of guilt. The client is asked to identify all possible factors influencing an outcome and to assign a percentage to each one, including his or her own intervention. Then a pie chart with all influences is made, leading to a more balanced view.

Role Reversion in Disputing Cognitions

Therapist and patient may switch roles in debating thoughts and beliefs. The therapist defends the patient’s hypothesis and the client has to challenge the cognition as if he or she were the therapist. This generates a playful attitude toward cognition, facilitating distancing and helping the client act as if he or she does not believe the cognition.

Capsule Summaries

Psychotherapy is, in many ways, a learning process. It is not wise for therapists to simply assume that clients, like students, will understand the full implication of a certain intervention, no matter how brilliant and clear it may seem to the therapist. Therefore, cognitive therapists are expected to ask their clients to make capsule summaries of what has been discussed in session, with a special emphasis on the conclusions that were attained. These summaries should capture the new perspective

that has been discussed. A panic patient, for example, may say, "After all we have discussed in this session, it is now clear for me that, even if they are unpleasant, panic attacks are not a danger to my health."

Flash Cards

Cognitive theory predicts that cognitive biases are activated by certain stimuli in specific contexts. Faulty beliefs about health are triggered in panic patients when they experience increased arousal. Depressed clients lose faith in their personal competence when faced with a challenge. Clients with generalized anxiety disorder have increasing negative thoughts when they lose contact with their loved ones. People with social anxiety have increasing negative thoughts about how they come across in social situations. All these beliefs or thoughts are challenged in therapy, but naturally clients find it more difficult not to believe them when in the critical situation. In order to improve access to functional cognition, clients write down on index cards the most important conclusions attained in therapy. They then carry these cards with them and look at them when they are facing the critical situation. Reading the functional alternative to the dysfunctional cognition dramatically increases the client's chances of not activating the usual problematic pattern of emotion and behavior.

Behavioral Experiments

As Bennet-Levy, Westbrook, Fennell, Cooper, Rouf, and Hackmann (2004) point out, it is easy to lose sight of how radical the concept of behavioral experiments is in the context of the history of psychotherapy. Indeed, most forms of psychotherapy in the 20th century assumed that in-session dialogue was the most important, if not the only, means to bring about change. Early behavior therapy posited that doing things differently is a powerful way of bringing about change in cognition and affect. Beck's cognitive therapy (1967, 1979) introduced the idea of using experiments to test the beliefs of patients. The dysfunctional cognition is treated like a scientific theory that must be based on solid empirical evidence. Faulty beliefs often suggest a pattern of behavior that prevents the person from obtaining evidence that would prove the belief false.

Bennet-Levy et al. (2004) give the following operational definition: "Behavioral experiments are planned experiential activities, based on experimentation and observation, which are undertaken by patients in or between cognitive therapy sessions. Their design is derived directly from a cognitive formulation of the

problem, and their primary purpose is to obtain new information which may help to: a) test the validity of the patient's existing beliefs about themselves, others and the world; b) construct and/or test new, more adaptive beliefs; and c) contribute to the development and verification of the cognitive formulation" (p. 8).

The goal of behavioral experiments is to bring about cognitive change in a way that makes new perspectives more believable. This may be achieved via experiential learning, emotional arousal (facilitating emotional processing), the encoding of experiences in memory in different ways, the practice of new plans and behaviors, or learning through reflection (Bennet-Levy et al., 2004).

There are two kinds of experiments: (1) active experiments, in which the patient takes the lead role, and (2) observational experiments, in which the client is an observer and a data collector, but not an actor. Active experiments involve acting in different ways in contexts in which a problematic behavior has been identified. They are used in real or simulated situations (e.g., role-plays) to test the validity of cognitions. Simulations are helpful when patients are wary about making changes in real life or when the real situation is rare.

A client had the belief "If I confront my teenage daughter, she will be very upset and I will lose her love." He was instructed to choose a situation in which he felt slightly unhappy about her behavior and to express his disagreement. The client's prediction was that she would react angrily at him. To his surprise, his daughter's reaction was actually quite the opposite.

Observational experiments are particularly useful when the thought of direct action provokes high anxiety or when more information is needed before an active experiment can be planned. For example, a patient who is very afraid of the consequences of fainting in public may accompany her therapist to a department store, where the therapist pretends to faint in a busy area, while the patient watches from a "safe" distance (C. Botella, personal communication, 2005).

When planning experiments, therapists must keep in mind a number of issues. The purpose of the experiment has to be very clear to the patient, the cognition to be tested must be very clear, and the degree of belief must be assessed prior to the experience. Therapists identify alternative perspectives and decide on the type of experiment that is best suited to the situation, anticipating potential problems and identifying solutions.

Experiments should be designed so that they are useful irrespective of the outcome of the experience ("no lose" experiments). A client was very fond of one of his classmates but made no move because he thought

rejection would be too painful. Although the first cognition, “She is not interested in me,” was proved correct, the client found that rejection was by no means as difficult as he thought, thus proving the second cognition wrong.

It is crucial to agree with the patient on how the outcome is to be assessed. It is not the experience in itself but the meaning assigned to it that is crucial to cognitive modification. Therapists must not take for granted that clients will make functional conclusions out of an experience unless potential outcomes are discussed beforehand.

Experiential Techniques

Cognitive-behavioral interventions usually involve experiential techniques that originated in other forms of therapy. Role-plays, empty-chair exercises, psychodrama, and imagery are some of the techniques that are most commonly employed. The techniques themselves vary not in the way they are applied, but rather in terms of the goals that the cognitive therapist wants to achieve. Experiential exercises are frequently used in CBT to test hypotheses, to help the patient feel differently about a belief, and to trigger an emotion in order to help with its processing.

CASE EXAMPLE

Jimena is a 22-year-old woman who has been referred by a psychiatrist who assessed her and diagnosed panic disorder and agoraphobia of mild to moderate severity and recent onset. The psychiatrist also prescribed a modest daily dose of clonazepam to be used during an imminent family trip but made it quite clear to the patient and her family that this was aimed solely at symptom control to make the trip possible. He also suggested to them that CBT was the best treatment option for her condition.

The assessment interview with her psychotherapist revealed that about 2 months before, she had attended a party where she drank heavily and smoked marijuana. She suddenly felt very dizzy and thought she would faint 3 times. The experience was very unpleasant: she had palpitations and a racing heart, a feeling of choking, a sense of unreality, and fears of dying or of going crazy. Similar experiences occurred over the following days in different situations, particularly when she was in a car with someone else at the steering wheel. These symptoms motivated the consultation with the psychiatrist. For the last weeks she has been very worried about

the possibility of experiencing the symptoms again. In order to avoid that, she has stopped taking buses. She continues to use the train regularly to attend classes at her college, but with a level of discomfort that extends to situations in which she feels “it would not be easy to escape.”

She also reports difficulties speaking (or singing) in public and occasionally in interpersonal interactions, meeting criteria for circumscribed social anxiety disorder. She is not as assertive as she would like to be and uses avoidance as a strategy to deal with interpersonal problems. She sees this as a flaw in her personality, not as a disorder. Also, she reports being uncomfortable with unexpected events in general, always searching for certainty. Her mood is not compromised; she is, in fact, a cheerful young woman with good social skills and a considerable social network.

Jimena’s typical automatic thoughts were “I am going to faint and something bad will happen to me,” “I am going to go crazy,” “I am going to have a heart attack,” “I will never get well, I will never be the same again,” and “These experiences are out of my control.” Her core beliefs about herself were “I am (physically) vulnerable,” “I am not a strong person.” Beliefs about others were “Others are strong and assertive” and “People are very critical of others.”

Underlying assumptions (intermediate beliefs) were “Because of my vulnerability, I must be very vigilant about any unusual bodily sensations,” “If I am not cautious, something terrible will happen to me,” “Since I am weak, I must avoid confrontation,” “If I make a mistake in public, they will humiliate me.”

The assessment interview includes some basic psychoeducation about anxiety. Her mother is present because Jimena did not dare come to the session by herself, so she is included in the psychoeducation. This is a good way of reducing negative, invalidating remarks from family members, who are normally baffled by agoraphobic behavior and may interpret it negatively. Jimena and her mother are asked to read the excellent psychoeducational material by Craske and Barlow (1993, pp. 25–28) for homework.

The following session begins with the discussion of the homework assignment and comments on the doubts and conclusions generated by the reading. According to the cognitive formulation of panic disorder (Clark, 1986), the afflicted person fears normal bodily sensations because they are catastrophically misinterpreted as signs of impending disaster (e.g., dying, going crazy). The catastrophic interpretation of the client’s autonomic activation is based on some dysfunctional beliefs, some of which are based on misinformation

about human physiology. Clients typically believe that strong emotions can be lethal, that a feeling of pressure in the center of the chest means choking or that anxiety itself is dangerous. Cognitive theory holds that providing information about the physiology of anxiety can lead to the correction of these faulty beliefs. Thus, every sensation described by the patient is explained as part of the normal course of anxiety: muscle tension is explained as something indispensable for implementing

the fight-or-flight response, an accelerated heartbeat is the result of the need to ensure optimal muscle function and prevent cramps, hyperventilation is a means of incorporating more oxygen, and so on. According to Clark's (1986) intervention for panic disorder, a whole cycle of panic is drawn with the patient in session, as in Figure 22.1 (see also Wells, 1997).

The aim of this technique is to help the client formulate a new way of looking at the experience of panic.

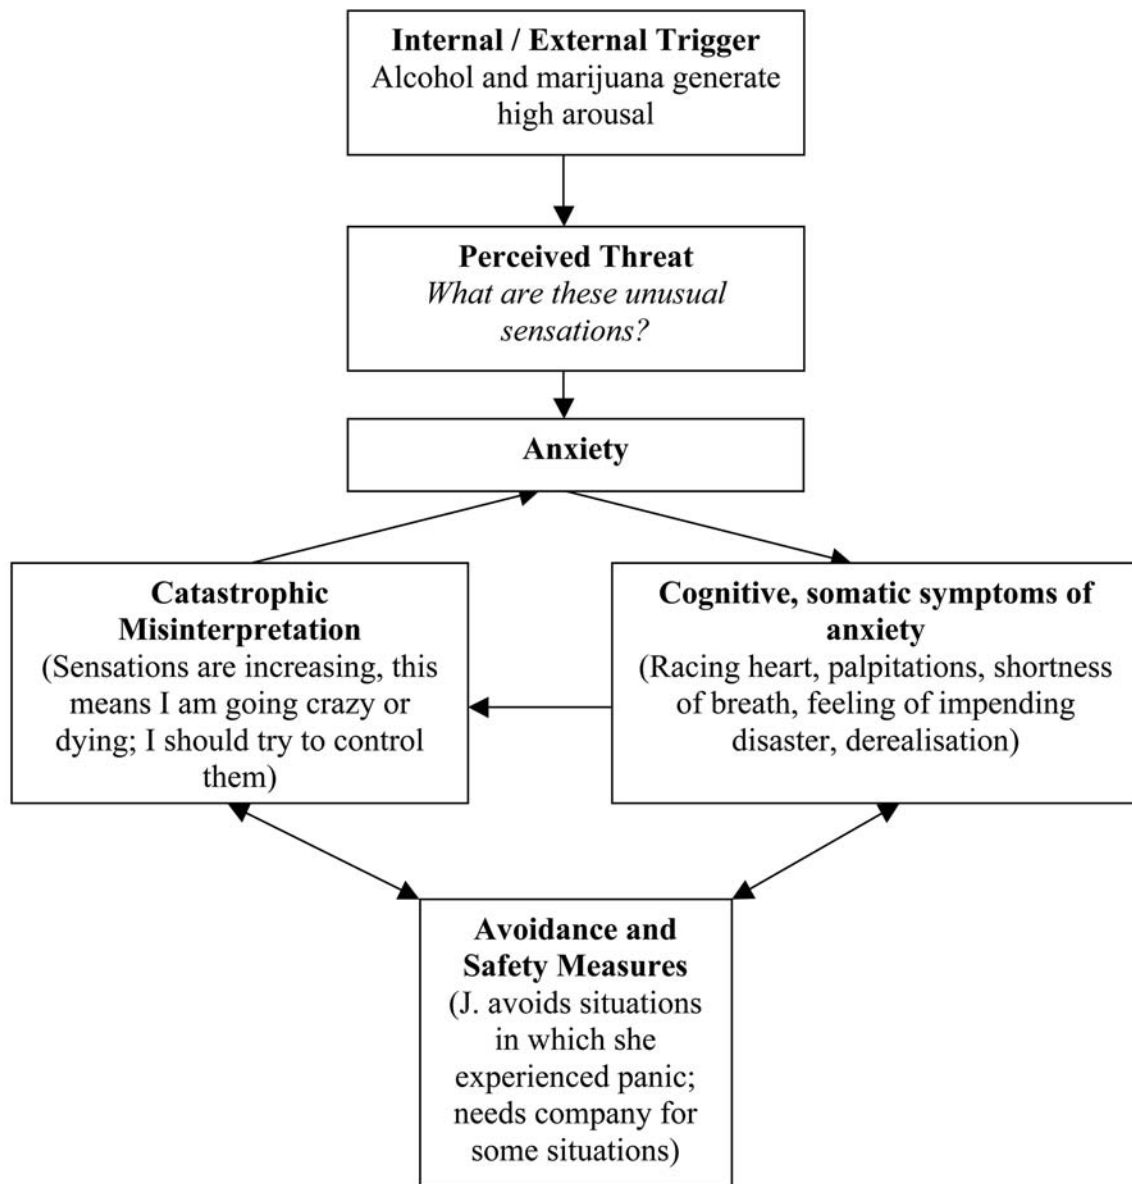

Figure 22.1 Cognitive model of panic.

From *Cognitive Therapy of Anxiety Disorders: A Practice Manual and Conceptual Guide*, by A. Wells, 2000, Chichester, UK: Wiley.

The therapist does not attempt to change the experience itself; he or she rather strives to develop a new, non-threatening way of looking at the same experience.

In this treatment, breathing retraining or relaxation is not used because the main objective is not to alleviate anxiety, but to help the patient gain a new perspective on the experience of anxiety and panic. Relaxation and controlled breathing can actually be safety measures (behaviors) for some panic clients (especially for those with fears of losing control; Barlow, 2002).

Jimena is asked for her consent to carry out an experiment at the following session. She and the therapist will hyperventilate for 60–90 seconds and then share their experiences. The client is told that in this way they can generate sensations similar to the ones she had during panic attacks, but at a lesser level and within her control. The therapist does it at the same time to prove to the patient that he or she believes there is no danger in hyperventilating. Some treatments of panic (Barlow, 2002) use this as a presentation of interoceptive exposure, a technique by which the patient is exposed to the feared sensations in order to achieve desensitization.

Then, the cognitive element in the cycle of panic is emphasized, and Jimena is informed of the importance of paying attentions to what she thinks when she experiences high anxiety and panic. The connection between cognition and emotion is explained, and her homework is to record her thoughts in previous episodes or in any new ones. She is also asked to make a hierarchical list of feared situations. This list is needed so the therapist can design graded assignments for dealing with agoraphobic avoidance.

The following session begins with a review of the homework. Jimena discusses her records of previous episodes and a number of new ones she experienced (milder than previous ones) during the week. Once the therapist is sure that she understands the connection between thoughts and emotions, the use of the daily thought record is introduced. She is instructed to use the daily thought record not only for recording but also for collecting evidence in favor of and against the thoughts that come up when she experiences high anxiety. Jimena is told that if she takes a critical look at threatening thoughts she will find out that they do not make much sense. When these thoughts are activated, the new conclusions are activated as well, and then the anxiogenic thoughts are not so believable, resulting in less anxiety.

As previously agreed, a hyperventilation experiment is conducted during the session. Jimena recognizes that the sensations are very similar to the ones she experiences when panicky. She concludes that they do not

come out of the blue, as symptoms of an unknown illness; they are just the result of arousal that has been triggered by some undetected stimulus (marijuana, coffee, a threatening thought, etc.).

The therapist reviews the list of feared (agoraphobic) situations and explains the principle of graded in-vivo exposure to Jimena. The therapist then proceeds to design an experiment in which the client will expose herself to the less feared situation, dropping all safety measures. Jimena must carry out the experiment long before or after taking the anxiolytic medication, because benzodiazepines can interfere with exposure and may be construed as safety measures.

She is also told to pay attention to and record the anxious thoughts that are likely to appear during exposure. Finally, she is instructed to report her results to the therapist via e-mail, in order to use this opportunity for troubleshooting and for assigning new graded exposure exercises. The aim of this technique is not just desensitization, but also testing the hypothesis “The only way of not feeling anxious is escaping the feared situations.” Exposure is thus used as a disconfirmation experiment.

At the following session, Jimena and the therapist review the homework. To her surprise, exposure to feared situations led to a sudden drop in anxiety. She has registered a number of negative thoughts that appeared just before the exposure experiment and in a couple of other situations over the week. She has managed to challenge the thoughts and makes the remark, “They are always the same thoughts.” This observation is used to go back to the issue of core beliefs, represented by repeated themes in automatic thoughts. The core belief “I am physically vulnerable” is inferred from the daily thought record, discussed, and challenged in session. Jimena is instructed to continue doing this over the week as homework. The therapist then moves on to the thoughts triggered by speaking in public and asks Jimena to apply the daily thought record in session to them. In discussion of the issue of collecting evidence in favor of and against the thoughts, the client is warned about confusing what people actually say with what she believes they are thinking (mind reading).

Mind reading provides a common source of “evidence” of the client’s social incompetence, so special attention must be devoted to it. Jimena is encouraged to carry out some exposure experiments (making a remark during a lecture at school) and pay attention to what happens. At the following session she reports no panic experiences during the week. It is agreed that Jimena will withdraw from medication over the following 2 weeks. If patients attribute their improvement to med-

ication alone, there is the risk of recurrence of panic disorder in future stressful situations. Therefore, testing the idea “I can manage on my own without medication” is important.

The rest of the homework is reviewed: Jimena has made a couple of remarks in class and nothing negative has happened, although she felt anxious when speaking. She has registered some negative automatic thoughts (“They will say it is a silly remark,” “I will look like a fool”) and has adequately challenged them. The therapist asks Jimena to pay special attention to the fact that the anxiety she felt was due to *what she expected* from the situation, but the outcome was quite different. The therapist emphasizes that it is the outcome that matters, rather than the internal experience (one could feel very confident and self-assured yet be met by negative reactions).

Jimena is instructed to pay attention when she engages in minor disagreements, in order to practice being assertive and observe the outcome. She has made progress with agoraphobic situations. The therapist asks her to increase her “comfort area” by taking alternative means of transportation to get to school. At the following session Jimena reports not missing the clonazepam; she has actually not given much thought to it in the past few days. She has made continuous progress with agoraphobic symptoms: she uses transportation normally within the city. She is asked to consider taking a bus or going by car somewhere outside the city to continue exposure.

There are no records of situations in which she has felt panicky. However, Jimena did feel quite anxious when she expressed disagreement with someone’s point of view during a lecture. Normally this would have meant that it was better to avoid those situations, but now she realizes that there may be a difference between what her mind or emotions say (the internal experience) and what the environment says (others’ responses to disagreement). She says she feels a bit stronger after having experiencing this. The belief “I am weak” is discussed. Jimena says her sister is very assertive, sometimes to such a point that she is sort of embarrassed by her behavior. The therapist points out that there is no need for her to behave like that but uses the opportunity to highlight the fact that, contrary to Jimena’s belief, people do not always respond negatively when people are very assertive. The client is still too afraid to sing in public, though, so that is left for future experiments. To take a graded stance in this matter, she is asked for the time being to lend some people recordings of her singing and see what the response is. Finally, cognitive work with automatic thoughts and

beliefs is reviewed, which shows progressive credibility of functional cognitions.

At the following session the review of homework indicates continued progress, with the exception of the assignment to give recordings of her singing to people. Jimena says she forgot about this part of homework and at the same time she did not feel like doing it when she remembered. The therapist and the client review the thoughts behind the ambivalence around completing the homework and agree that it will be completed for the following session. Because of the steady progress, this session is scheduled for 2 weeks from now.

The review of homework for the next session is positive: Jimena has completed all the usual records satisfactorily and has also given recordings of her singing to a couple of friends. She has not gotten feedback from them so far and anticipates rather negative responses, despite frequent her sisters’ frequent compliments on her skills as a singer.

The client has been off medication for quite some time now and has not reported any inconvenience or marked anxiety.

Jimena is asked to work on a treatment outline indicating what has worked for her and what she has learned in therapy. The following session is scheduled for 2 weeks from now. Jimena and the therapist meet for the final session, during which they work on the treatment outline. Jimena has listed thought records and experiments as helpful strategies. She also lists the alternative beliefs developed in therapy.

The therapist explains what to do in the case of eventual recurrences, what their usual triggers are, and what to expect in terms of the probability of future problems. Given the recency of onset, the mild severity of symptoms, and the good response to treatment, the chance of relapse looks pretty small. The therapist compliments the patient for her achievements and expresses satisfaction with the good work they have achieved as a team.

RESEARCH AND EFFICACY IN CBT

CBT, with its reliance upon experimental methods, is constantly evolving; its models are constantly being validated, tested, and refined. The firm foundation of CBT in the research base of psychiatry and clinical psychology might partially explain its robust clinical utility, which has resulted in ongoing adaptation of CBT to an increasingly wide range of disorders and problems (A. T. Beck, 1997). Compared to other psychotherapy

modalities, cognitive-behavioral therapies are exceptional, with their wide and clearly dominant presence among empirically supported therapies for a variety of mental disorders (Butler, Chapman, Forman, & Beck, 2006; Chambless et al., 1996; Chambless & Hollon, 1998). CBT has been the subject of numerous clinical trials; between 1986 and 1993 the results of 120 clinical trials were added to the literature. A recent review of meta-analyses of treatment outcomes of CBT for different 16 mental disorders (Butler et al., 2006) supports its efficacy. CBT has been shown to be highly effective for recurrent adult and adolescent depression, panic disorder with or without agoraphobia, generalized anxiety disorder, social phobia, post-traumatic stress disorder, and childhood depressive and anxiety disorders. For treatment of all these disorders, large effect sizes have been found. For treatment of anger, marital distress, childhood somatic disorders, and chronic pain, effect sizes were in the moderate range when CBT was compared to controls. Large uncontrolled effect sizes were obtained for treatment of bulimia and schizophrenia. Cognitive-behavioral treatments have also been applied successfully to addictive disorders, insomnia, paraphilias, and personality disorders. In the discussion that follows we will briefly describe the findings regarding most common clinical problems—anxiety and affective disorders—and we will outline the evidence of efficacy of CBT in schizophrenia, a disorder that, not long ago, was regarded as susceptible to only biological intervention. A more extensive review of clinical application and efficacy of CBT is beyond the scope of this chapter, and readers interested in empirically validated CBT treatment are referred to other publications (e.g., Chambless & Hollon, 1998; DeRubeis & Crits-Christoph, 1998; Nathan & Gorman, 2002).

Mood Disorders

There is evidence that CBT is better than a pill-placebo and equivalent to antidepressant medications (Elkin et al., 1989; Hollon, DeRubeis, Evans, Wiemer, Garvey, Grove, & Tuason, 1992) not only for treatment of mild depression but moderate to severe depression as well (DeRubeis et al., 2005). CBT is as effective as medications in acute treatment but seems to have better enduring effect than pharmacotherapy, which reduces subsequent risk of depressive relapse after discontinuation of treatment (DeRubeis & Crits-Christoph, 1998; Gloaguen, Cottraux, Cucherat, & Blackburn, 1998). Results of a recent multisite clinical trial (Hollon et al., 2005) indicate that cognitive therapy had durable effect

for moderate to severely depressed patients equivalent to the effect of maintenance of medication treatment. Review of meta-analyses (Butler et al., 2006) revealed that CBT is as effective as behavior therapy in adult depression and obsessive-compulsive disorder.

There is also evidence that CBT in conjunction with medication is efficacious for treatment of bipolar disorder (Lam et al., 2003; Perry, Tarrier, Morris, McCarthy, & Limb, 1999). Patients on combined CBT and mood stabilizers showed fewer and shorter bipolar episodes (Lam et al., 2003) and fewer hospitalizations (Cochran, 1984; Lam et al., 2003) and demonstrated better medication compliance (Lam, Bright, Jones, Hayward, Schuck, Chisholm, & Sham, 2000) and higher social functioning (Lam et al., 2003) than patients taking medications alone.

Schizophrenia/Schizoaffective Disorder

CBT has shown promising results as an adjunct to pharmacotherapy in the treatment of schizophrenia (Butler et al., 2006; Turkington et al., 2008). Its efficacy in treating acute psychotic episodes (Drury, Birchwood, & Cochrane, 2000; Drury, Birchwood, Cochrane, & MacMillan, 1996; Lewis et al., 2002), chronic medication-resistant positive symptoms of both schizophrenia (Turkington et al., 2008) and schizoaffective disorder (Martindale, Mueser, Kuipers, Sensky, & Green, 2003), and chronic negative symptoms (Rector, Seeman, & Segal, 2003) and in prevention of future psychotic episodes (Gumley, O'Grady, McNay, Reilly, Power, & Norrie, 2003) has been established. Moreover, it has been demonstrated that CBT, either in conjunction with medication (McGorry et al., 2002) or without it (Morrison et al., 2002), may delay the onset of the first episode of the disorder.

The five- and eight-year follow-up of family CBT (Tarrier, Barrowclough, Porceddu, & Fitzpatrick, 1994) showed protection against relapse, but only in the high expressed emotion group, whereas the five-year follow-up of CBT reported by Drury et al. (2000) failed to demonstrate stable effects except in those who did not relapse.

Anxiety Disorders

The effectiveness of CBT for generalized anxiety disorder was evaluated in a meta-analysis by Gould, Buckminster Pollack, Otto, and Yap (1997). They reported that CBT outperformed no-treatment conditions, wait-list controls, nondirective therapy controls,

and pill-placebo controls and had effectiveness similar to that of medications. Positive results of CBT were maintained through at least 6 months post-treatment (Gould et al., 1997) and were shown to be persistent as far as 8–10 years later, as more recent reports indicate (Durham, Chambers, MacDonald, Power, & Major, 2003).

Many studies support substantial efficacy of CBT in panic disorder (with and without agoraphobia). David Clark (1996) reported that across five studies, between 74% and 95% of panic patients treated with CBT became panic free, and that this effect was maintained at 6–15 months of follow-up. In these trials CBT was superior to wait-list control, applied relaxation, and pharmacotherapy. Meta-analysis done by Gould, Otto, and Pollack (1995) revealed that CBT had the highest effect size compared to pharmacological treatment and combined treatment. Among the CBT interventions, combined cognitive restructuring with interoceptive exposure showed the strongest effect size.

Cognitive models of social phobia (Clark & Wells, 1995) emphasize that its occurrence and maintenance are mediated by maladaptive beliefs about social performance. Two meta-analyses of CBT treatments for social phobia revealed that cognitive therapy is superior to wait-list and placebo attention controls, and similar to exposure treatment without cognitive restructuring and the combination of the two interventions (Feske & Chambless, 1995; Gould et al., 1997). Barlow (2002) indicates, however, that combined cognitive restructuring and exposure treatment is better than the two interventions alone. There is also evidence that such a combined treatment delivered in a group context over 12 weeks is more effective than placebo pills and non-specific therapy and as effective as medications (Heimberg et al., 1998).

There is growing evidence that CBT is as effective as exposure and response prevention in treatment of obsessive-compulsive disorder (Abramowitz, 1997), although the latter treatment is broadly considered the psychotherapy treatment of choice. In a recent controlled clinical trial, Rector, Richter, Denisoff, Crawford, Szacun-Shimizu, and Bourdeau (2005) indicated that the combination of cognitive therapy plus exposure and response prevention is superior to exposure and response prevention alone in the treatment of medication-refractory obsessive-compulsive disorder. Cognitive therapy seems to work best for the obsessive-compulsive disorder subgroup with mental obsessions (Steketee & Barlow, 2002). There is evidence that CBT is effective with or without concomitant pharmacother-

apy with SSRI (Franklin, Abramowitz, Bux, Zoellner, & Feeny, 2002).

CONCLUSIONS AND FUTURE DIRECTIONS

In the last 30 years a variety of therapy strategies have been developed under the name of CT and CBT. A great number of studies have shown them to be an effective treatment for a variety of psychiatric disorders in children, adolescents, and adults, and some of them, for example, CBT for panic disorder and depression in adults, have become established as empirically supported treatments. One of the greatest achievements of CBT has been the development of well-articulated intervention packages for a range of clinical disorders, which facilitated outcome research of CBT and its dissemination. Much current research aims to further disseminate and improve existing cognitive-behavioral interventions. Substance abuse, schizophrenia, personality disorders, bipolar disorders, and anorexia nervosa are among the clinical problems receiving recent empirical attention. There are various trends in ongoing research in CBT, among them (1) adoption of clinical protocols for a variety of patients with comorbid psychopathology, which might satisfy growing community needs; (2) consideration of cost-benefit analyses; (3) the development of highly reliable and valid measures of cognitive functioning in clinical disorders, including information-processing paradigms of experimental methods; and (4) the development of combinations of different treatment modalities and interventions, for example, the third wave of therapies, which unite CBT methods with mindfulness and acceptance-based interventions. There is a need to carry out more clinical trials comparing the efficacy of traditional CBT methods using rational reasoning with third-wave CBT methods. Of particular interest would be verifying if patients can disengage from negative thinking without correcting its biased content, and if such procedures bring about change in appraisals of thoughts. Further research is required to establish what the exact mechanism of change is in CBT, and who is most likely to benefit from it.

Clinical Psychopharmacology: Origins, Research, and Practices

Kathy Scott-Gurnell

Toi B. Harris

Patricia M. Averill

Psychopharmacology is the use of medications to treat psychiatric illnesses. The medications utilized in the treatment of mental illness vary in that some may cure the illness, some may maintain the symptoms, and others curtail target symptoms of the treated condition. Psychopharmacology is only one of the many interventions utilized by psychiatrists in the treatment of their patients because mental illnesses are very complex and often affect the brain chemistry, mental status, physical health, socialization, occupational functioning, and family dynamics of a patient. Because of the complexity of mental illness, it is essential that psychopharmacology not be “oversimplified to a one diagnosis—one drug approach” (Sadock & Sadock, 2003, p. 974). Many medications used in psychiatry are utilized for more than one type of psychiatric disorder, and even more are used as a standard “off label” treatment for a variety of symptoms. “Off label” refers to the use of a medication for an illness or at a dosage that was not approved by the FDA and not discussed in the package insert for the medication. The Federal Food, Drug, and Cosmetic Act authorized the FDA to control and approve the release of drugs for medical use once they are proved safe and

effective. Before medications can be released for medical use in the United States, they must be investigated in three separate phases:

Phase I—The initial introduction of the drug to human subjects. The subjects for these studies are usually healthy volunteers, $n = 20\text{--}80$ subjects. The goal of these studies is to determine metabolic and pharmacological actions of the drug in humans, side effects with increasing dose and if possible effectiveness.

Phase II—The studies in this phase are controlled clinical studies designed to obtain information about the effectiveness of the drug for particular indications. Common side effects and risk associated with the drug are determined, $n =$ several hundred subjects.

Phase III—These studies are designed to gather more data on the effectiveness and safety of the drug as well as evaluated for benefit-risk relationship. This phase also provide data to extrapolate the results to the general population as well as identify data for the physician labeling, $n =$ several hundreds to several thousand subjects. (U.S. Food and Drug Administration, 2001)

Once a medication is released by the FDA, physicians can utilize their medical expertise in deciding to use a dose above the FDA recommendations and to treat conditions other than the labeling indications without violating the Federal Food, Drug, and Cosmetic Act (Sadock & Sadock, 2003).

HERBAL ORIGINS

The use of plants to cure illness is the foundation of herbal medicine. This form of medicine originated in 4000 BCE in China and continues to be integral to modern Chinese medicine. Greco-Roman medical texts also describe the use of over 500 plants and herbs to treat disease (Sadock & Sadock, 2003). Currently, in the United States, it is estimated that over a million dollars per year is spent on herbal medicine (Sadock & Sadock, 2003). This is problematic because relationships between FDA-approved medication and over-the-counter supplements have not been fully defined or clarified. Also, the fact that herbal treatments are available without prescriptions has assessment and treatment implications. In 1998, the legislature mandated the creation of the National Center for Complementary and Alternative Medicine to investigate and validate complementary and alternative medicine treatments, disciplines, and systems as well as other areas of concern (Straus & Engel, 2000).

Although the term “alternative treatments” is commonly used, “complementary and alternative medicine” is a more appropriate term since most herbs are used to complement conventional treatments (Straus & Engel, 2000). Because of this, it is very important for clinicians prescribing medication to understand that plants and herbs were the origin of medicine and are still used today, either as complementary or alternative treatments. Herbal treatments have mechanisms of action, biochemical ingredients, and most importantly side effects that are very similar to those of conventional treatments. Therefore, clinicians must evaluate their patients’ knowledge and use of plants and herbs throughout their treatment. The following case example is a good illustration of this.

Case Example

Ms. C. suffered recurrent depression for more than 10 years. During her pregnancies, she would stop her Prozac and continue to be monitored in weekly or biweekly therapy sessions. During her third pregnancy, after collaboration with her obstetrician, she was allowed to

take St. John’s wort in her second trimester. According to the treatment plan, Mrs. C would stop taking the St. John’s wort during her last month of pregnancy and immediately restart the Prozac after the baby’s delivery; she was not planning to breast-feed. In efforts to provide continuity of care, the obstetrician restarted the Prozac before Ms. C. was discharged from the hospital. However, when Ms. C. followed up with her psychiatrist, she presented with agitation, tachycardia, diaphoresis, nausea, vomiting, diarrhea, dilated pupils, and rigidity. Immediately, the psychiatrist was concerned that the dose that had kept the patient stable for so many years was suddenly causing signs of toxicity. To confirm the suspicion, Ms. C. was questioned about her current medication regimen. She confirmed that she feared the onset of action of the Prozac would take too long, so she had continued to take the St. John’s wort 3 times a day, along with the Prozac. This history explained the reaction.

Diagnosis

Ms. C. developed serotonin syndrome by taking Prozac 20mg in conjunction with St. John’s wort. Serotonin syndrome is a potentially dangerous syndrome that can present when a patient is taking more than one serotonergic agent (Canan, Korkmaz, Kocer, Onder, Yildirim, & Ataoglu, 2008). After 1 week without the St. John’s wort and taking Prozac alone, the symptoms abated. In spite of this serious reaction, there are times when treatment with herbs in place of conventional medications may be preferred by patients. For example, a patient diagnosed with mild to moderate depression may prefer psychotherapy alone or St. John’s wort over a conventional antidepressant, and it may be completely reasonable to try this initially. Patients do have autonomy and the right to participate in and make choices about their treatment. Mild to moderate depression can sometimes resolve with St. John’s wort (Nierenberg, Mischoulong, & DeCecco, 2002). Regardless of the treatment plan, appropriate monitoring of the patient’s mood symptoms to ensure no decompensation is indicated and necessary. In addition to monitoring the patient’s history and experience with complementary and alternative medicine, it is also essential to verify any other medications patients are taking along with natural substances. Self-medication with alcohol and/or street drugs is very common among individuals suffering from mental conditions. Because of the high comorbidity of mental illness and substance use disorders, the authors’ preference is to refer to drugs used for treatment as medications and

reserve the term “drugs” for street drugs. This became important in practice after hearing so many patients say, “I do not want to use any drugs” (meaning medications), because of their concern about or prior history or experience with street drugs. Patients often assume that all “drugs” are addictive, including all prescribed psychotropic agents. This chapter will focus on psychopharmacology and the use of medications for psychiatric conditions. We have explored the herbal origins, but before moving forward, we will explore the origins of psychopharmacology and the original thinkers in psychiatry who contributed to its development throughout the years.

ORIGIN OF CONVENTIONAL PSYCHOPHARMACOLOGY

The history of psychopharmacology is fascinating yet very revealing of the conflict and misconceptions, both intrinsic and extrinsic, regarding the treatments offered by psychiatry. Two schools of psychiatry—namely, psychoanalysis and the biological bases of behaviors—have offered different approaches to the treatment of psychiatric illness. The first focused on psychotherapy and the internal processes of patients, while the other emphasized the neuroscience and biochemical processes of illness. Eric Kandel (1998) has illustrated the resistance to the biological approach in the treatment of psychiatric illness. Kandel, who trained at Harvard Medical School in 1960, described the attitudes of the faculty regarding research and medication during the era of psychoanalysis. Kandel reported that he and fellow residents were discouraged from reading textbooks and scientific literature, as faculty feared that the intellectual stimulus would interfere with their ability to focus on their patients. He discussed how some of the prestigious psychiatry programs’ reluctance to engage in the research world, along with the slow development of the brain sciences, led to the ostracism of psychiatry by the other medical fields (Kandel, 1998).

During this time, other psychiatrists were searching for the biochemical factors that influence mental illness. In the 1950s and 1960s, psychiatrists began to investigate the role of monoamine agents in the psychopathology and treatment of psychiatric illnesses. Cameron (1999), who described “the monoamine theory” in his article entitled “Psychopharmacology,” suggests that because monoamines (such as the catecholamines—norepinephrine, epinephrine, and dopamine—and the indoleamine serotonin) were the agents identified in neural tissue, peripherally and centrally, they became

the target of early studies. Results of these studies suggest that dopamine is associated with schizophrenia, and epinephrine, norepinephrine, and serotonin with depression and anxiety (Cameron, 1999). Subsequent studies have supported this theory in that medications that deplete monoamines, reserpine and B-adrenergic agonists, often result in increased depressed mood (Cameron, 1999). Likewise the excess of dopamine leads to psychosis, and most antipsychotic medications lower the levels of dopamine in the brain. This implies, per Cameron, that excess dopamine is not unique to schizophrenia but occurs in any psychotic process regardless of the disorder. This explains why antipsychotics are just as effective with psychosis in depression, mania, and even not-otherwise-specified psychosis. Amino acid neurotransmitters such as GABA and glutamate play a role as well as histamine and acetylcholine, although much less than the monoamines (Sadock & Sadock, 2003). Pharmaceutical companies to date utilize mechanisms of action that alter the brain chemistry of monoamines and amino acid neurotransmitters in the treatment of a variety of psychiatric illnesses. The medication tables throughout this chapter will support this theory.

Another illustration of the internal conflict in psychiatry during this period of rapid development is the fact that while many psychiatrists were investigating the use of pharmacology in the treatment of psychiatric illnesses, others were focused on the negative aspects, such as side effects. In 1961, when Polonio wrote about the “psychogenic disease,” he described the iatrogenic illness (illness caused by a physician) that psychiatric patients incur once they choose to take medications for psychiatric illness. He recorded the quotes of patients and their families. The wife of a patient stated, “He got well; he had no more anxiety and insecurity. But he has become cynical and egocentric, and he thinks only of pleasure. He is not so honest” (Polonio, 1961, p. 1426). This suggests that the patient did improve from the depression and anxiety he suffered but became very agitated and impulsive as a result of the activation qualities of the medication. Side effects and adverse effects continue to be a major concern in psychopharmacology. Because the medications we use in psychiatry are mind altering in their mechanisms of action, it is imperative that we discuss what to expect and teach patients to monitor for these effects. To appropriately inform patients, we ourselves must be knowledgeable about the medication and its potential side effects but also be familiar with the patient, his or her medical history, and any cultural variations that may put him or her at risk. In addition, we are reminded that we should

ask our patients on a regular basis about side effects. Parallels of today's FDA warnings could make this point for continuity in theoretical perspective and also from former to modern-day dilemmas.

Another conflict discussed by Polonio (1961) is the lack of communication between providers. He described how uninformed patients visit their primary care physicians to complain of side effects that were caused by their psychotropic medications only to get yet another diagnosis and medication for treatment of the side effect. The following vignette from a case in 2007 illustrates what Polonio described in 1961.

Patient Z is treated by his psychiatrist for attention-deficit/hyperactivity disorder with a stimulant that leads to upset stomach. He visits his primary care physician, who diagnoses him with dyspepsia, recommends a diet change, and prescribes an antacid agent. The psychiatrist who prescribed the stimulant, which is the cause of the GI distress, may not find out about the patient's additional diagnosis for several months. This patient is now being treated for two illnesses, although one is caused by the medication prescribed by the psychiatrist and should therefore be addressed in a different manner. In 1961, Polonio knew that psychiatric patients see a psychiatrist for mental symptoms and then go to their primary doctors for the side effects, resulting in additional diagnoses and unnecessary medications. In summary, as psychiatrists, we must assess and treat our patients from a holistic approach. This means asking about any new symptoms and any treatment received from other physicians.

MULTIDISCIPLINARY APPROACH TO TREATMENT

As psychiatrists, we are trained to approach treatment of our patients from a biopsychosocial-cultural viewpoint, which involves treating the biological, psychological, and social aspects of every patient while taking into consideration the cultural aspects contributing to the condition and treatment. Even as we study mental illnesses, we approach them from this multifaceted perspective. We realize that every patient is composed of genetic material that has predestined who they are and dictates what physical and mental conditions they may genetically harbor. We recognize that incidents such as head injuries, seizures, or exposure to substances may alter the individual's overall presentation in illnesses. Psychologically, we take into consideration their life experiences, including trauma, loss, or abandonment issues, which may also contribute to their symptoms

and presentation. We evaluate the defense mechanisms and personality traits they have developed in an effort to protect their egos from further insult. In addition, we consider their social situations, socioeconomic status, intelligence, academic and occupational achievements, family dynamics, and exposure to violence, sexual abuse, and substance abuse. Finally, we consider the culture in which the individual was reared and currently exists, religious beliefs, culturally biased beliefs regarding psychiatry and medication, and any known ethnic variations regarding metabolic response to certain medications. As psychiatrists, in spite of the current limitations of managed care, we are impelled to address our patient from this biopsychosocial-cultural perspective during each encounter.

So, given these challenges, how do we collaborate with our fellow mental health providers? This is a very crucial issue that must be addressed in order to ensure a comprehensive and effective treatment plan. Training for all psychiatrists includes working with a multidisciplinary treatment team. The psychiatrist is considered the leader of the team; however, a dictatorship is not productive. The approach returns to the biopsychosocial-cultural model, where the psychiatrist is the biological expert; the psychologist is the psychological expert; the social worker is the social expert; and, if present, a member of the clergy is the cultural/religious expert. This serves only as a model, as each clinician may train and take an interest in any or all of these areas. Psychiatrists possess an understanding of the psyche and normative development and vary in skill level with respect to psychotherapy. The psychologist likewise may choose to focus on neuropsychological testing; psychological testing; psychotherapy; research; and, more recently, psychopharmacology. Nurse-practitioners may focus on adult or family psychiatry and practice psychopharmacology and psychotherapy. The old cliché "Time is money" is driving us all to educate and prepare ourselves to be a one-stop shop for our patients, when possible. Likewise, if a patient's psychiatric condition is complex and resistant to standard care, the need to collaborate becomes essential. In this instance, each discipline is expected to contribute its expertise to the overall care of the individual patient. Knowledge of what each mental health provider is capable of contributing is essential. Moreover, if several professionals are providing the patient with care, it is important that channels for open communication exist.

The psychiatrist is taught to be the ultimate coordinator of care for the patient. Although the psychiatrist is the coordinator, there may be times when all

clinicians can work independently without the need for much communication. However, at other times, it may become necessary for the psychiatrist to be aware of treatment issues. For example, if the psychologist is involved in insight-oriented therapy with a depressed patient, depressive symptoms may be exacerbated and require an intervention from the psychiatrist. The intervention may require adjustments in medications, or the patient's condition may be too fragile to warrant insight-oriented therapy and consultation between the psychiatrist and psychologist on how to proceed may be necessary.

Although the need for multifaceted treatment and a multidisciplinary approach is recognized, the remainder of this chapter will focus on pharmacological treatment for psychiatric disorders.

PSYCHOPHARMACOLOGICAL APPROACHES TO MOOD DISORDERS

Mood disorders include two spectrums of illness: unipolar depression is one dimension of mood, and bipolarity—which consists of two poles, depression and mania—is the other dimension. Patients with mood disorders comprise a large percentage of patients seeking treatment from the entire spectrum of health providers. The lifetime prevalence of mood disorder is 20.8% and the median age is 30, as per the U.S. National Comorbidity Replication Survey (Kessler, Berglund, Demler, Jin, Merikangas, & Walters, 2005). The lifetime prevalence of major depression has been reported as 10%–25% for women and 5%–12% for men, and bipolar disorder as 0.4%–1.6% for men and women combined (American Psychiatric Association, 2000). Accurately differentiating between these two mood disorders is not always simple and can greatly hinder the treatment. Three factors that contribute to this hindrance are the following: first, many patients with mental illness are not seeking treatment; second, of the patients who do seek treatment, most of them do not seek treatment from a psychiatrist; and third, the majority of patients with newly onset bipolar disorder present for treatment in the depressive stage and do not even recognize their manic phase as a disorder.

Those patients who seek treatment for unipolar depression can be diagnosed relatively easily. Although depression may be rather straightforward and easily diagnosed, this may not be the case in bipolar depression, which often is masked by the patient's presentation and concerns during a depressive episode. Interestingly, 0.4%–1.6% of individuals presenting with depression

actually have bipolar disorder; however, most of them only seek mental health services when in a depressed state. This is one of the reasons that bipolar disorder is misdiagnosed and many individuals will not get an accurate diagnosis for up to 10 years (Hirschfeld, Lewis, & Vornick, 2003). Needless to say, the incorrect diagnosis can result in inappropriate treatment of the disease. It is important to gather an adequate knowledge base about mood disorders, because these individuals comprise 71% of completed suicides (Beautrais, 2003). On the continuum, there are numerous mood disorders classified in the *DSM-IV-TR*. Our discussion will focus on the two major illnesses, namely, major depressive disorder and bipolar disorder.

Case Example

Mrs. K is a 36-year-old female brought in by her husband, who is asking if we can help his wife. Mr. K reports that his wife is isolating in their bedroom, not dressing, and not wanting to be in the company of their two daughters. He reports that she is always tired, and even though she is always in bed, she is complaining of not sleeping well at all. Mrs. K notes that she is feeling sad and cannot stop crying, which leads her to isolate from her children. Mrs. K elaborates on the volatility of her emotions and relays that she is also very irritable and this causes her to isolate. She is not able to enjoy her family anymore, and she only attends mandatory outings. Previously, she was treated for depression in the past but was doing well until approximately 2 months ago. Mrs. K does admit to hopelessness and thoughts of suicide but denied any active plan or prior attempts. She also denies having any auditory or visual hallucinations, or delusions. Mrs. K does not have a history of decreased need for sleep, excessive energy, hyperreligiosity, or racing thoughts. An additional stressor reported by the family is that Mrs. K's teenage daughter recently revealed that she was sexually abused. This brought back Mrs. K's unresolved traumatic experience of being sexually abused as a child, as well as guilt that she did not protect her child. Ms. K. feels she should be able to handle the depression the way she handled that experience—by repressing it all and moving on.

Diagnosis

It is easy to see that Mrs. K does meet criteria for major depressive disorder based on the presence of six of the nine symptoms. Mrs. K's symptoms are causing severe functional impairment in terms of her role as a mother and wife and in her social life as well. However, it is

important to rule out other reasons for her symptoms. In evaluating the patient, the clinician should delineate if the symptoms are in the presence of a mixed episode of bipolar disorder. The symptoms also must be exclusive of drug use, medication, or medical conditions. Lastly, we must verify that a recent death is not the cause of the symptoms.

Treatment for Mrs. K was addressed from a biopsychosocial-cultural perspective. In terms of her psychology, we learned that Mrs. K was sexually abused as a child and has now learned that her daughter also has been sexually abused. Socially, Mrs. K has isolated herself from her friends and immediate and extended family. She is also not relating well with her husband and children, due to irritability. Culturally, Mrs. K is the middle child of two sisters, who want her to “snap out of this state” and take care of her husband and children. Mrs. K does not understand why she has not been delivered from the depression through prayer and her faith. Fortunately for Mrs. K, her husband is a psychiatric technician at a local hospital and he convinced her to seek treatment. Individual therapy is recommended, and Mrs. K also decides to have her oldest daughter assessed for depression.

Pharmacologically, we first review the medications Mrs. K has taken in the past. The success of prior medication is the best predictor of future success. This is also true of medication that successfully treated a first-degree relative. Other factors one must take into consideration when prescribing include the medication cost to the patient, the insurance formulary list, and the patient's biases, which often involves providing education, answering any questions, and dismantling any myths. For example, many patients believe that antidepressants are addictive. They base this on either the assumption that anxiolytics are antidepressants, the resurfacing of depressive symptoms when medication is prematurely stopped, or the rare but possible withdrawal symptoms that some patients experience when antidepressants are abruptly stopped. Other factors to consider include sleep disturbances, obesity, a loss of appetite, libido dysfunction from the depression, and a family history of bipolar disorder. Mrs. K was originally prescribed Paxil, which caused sedation. Subsequently, Lexapro successfully treated an episode of depression 2 years previously. Thus Lexapro 20mg is the medication of choice.

Medication Prescribing Trends

It is important to discuss the thought process of a psychiatrist who is selecting an antidepressant for his or

her patient. However, it is interesting to note that between 2002 and 2005, the number of prescriptions filled for antidepressant drugs increased from 154 million to 170 million, according to a report released by the U.S. government. The Agency for Healthcare Research and Quality found that 29% of antidepressant prescriptions (not including refills) were written by psychiatrists—medical doctors who specialize in the treatment of mental disorders. Twenty-three percent came from general practitioners—physicians who provide primary care but are not specialty trained. Twenty-one percent came from family practitioners—primary care physicians who have completed a residency in family medicine. Ten percent came from internal medicine specialists—physicians who complete a residency in internal medicine and who focus on the diagnosis and non-surgical treatment of adults with illnesses that are difficult to diagnose or manage. The data used for this analysis are from the Medical Expenditure Panel Survey of health services (Preidt, 2008).

Table 23.1 lists the common side effects, dose ranges, and neurotransmitter activities of a variety of antidepressants. It is very important to discuss the black box warning for children and adolescents taking antidepressants. These warnings are located in the package insert of all antidepressants, and clinicians are responsible for informing their patients of this information. A discussion regarding the increased risk of suicidal ideation with antidepressant treatment in children and adolescents is very important to ensure the patient is equipped with all the necessary information to give informed consent.

Other factors to investigate when treating with antidepressants include the risk of alcohol and drug use, as well as any medications prescribed or over-the-counter medications that the patient may be taking. Antidepressants such as Prozac are metabolized in the liver via the cytochrome P450 system. While Prozac, for example, occupies this enzyme system, other medications may be allowed to stay in the bloodstream longer and build up to toxic levels, which may cause unwarranted adverse effects with other medications taken. Finally, it is important to ascertain that patients treated with antidepressants do not harbor a bipolar mood disorder. Antidepressants alone in a patient with bipolar disorder can lead to extreme activation and even mania with psychosis.

As discussed at the beginning of this section, bipolar disorder can be one of the most difficult disorders to diagnose. Clinicians are frequently challenged by diagnostic dilemmas and the natural course of the illness. The majority of individuals with bipolar disorder, 75%

MECHANISM OF ACTION	BRAND NAME/ GENERIC NAME	DOSE RANGE AND DOSE FORMS	SIDE EFFECTS	INDICATIONS
Serotonin Reuptake Inhibitors (SSRI): Increase serotonin Block serotonin reuptake pumps Increase norepinephrine and dopamine transmission	Prozac/fluoxetine	20 mg to 80 mg Capsules: 10 mg, 20 mg, and 40 mg Tablet: 10 mg Liquid: 20 mg/5 ml Weekly: 90 mg	GI distress Sexual dysfunction Insomnia Apathy Agitation Headaches <i>Rare:</i> Seizures Mania Suicidality Weight gain Sedation	Major depressive disorder Obsessive-compulsive disorder Panic disorder Bulimia nervosa Premenstrual dysphoric disorder Generalized anxiety disorder Bipolar disorder (combined with Zyprexa, Symbyax) Social anxiety disorder Post-traumatic stress disorder
Serotonin Reuptake Inhibitors (SSRI): Increase serotonin Block serotonin reuptake pumps	Lexapro/ escitalopram	10 mg to 20 mg Tablets: 10 mg and 20 mg Oral solution: 5 mg/5 ml	<i>Same as above plus:</i> Hyponatremia (mostly in elderly) Bruising and rare bleeding <i>Rare:</i> Seizures Mania Suicidality Weight gain Sedation	Major depressive disorder Panic disorder Obsessive-compulsive disorder Post-traumatic stress disorder Social anxiety disorder Premenstrual dysphoric disorder
Serotonin Reuptake Inhibitors (SSRI): <i>Same as above plus:</i> Mild histamine antagonist Inactive isomer interferes with the active isomer	Celexa/citalopram	20 to 60 mg Tablets: 10 mg, 20 mg and 40 mg scored Liquid: 10 mg/5 ml	<i>Same as above plus:</i> SIADH (syndrome of inappropriate antidiuretic hormone secretion)	Depression Premenstrual dysphoric disorder Obsessive-compulsive disorder Panic disorder Generalized anxiety disorder Post-traumatic stress disorder Social anxiety

(Original edition, 2005)</div></div>				

of women and 67% of men, present with depressive symptoms (Sadock & Sadock, 2003). Of these individuals 40%–50% will have a manic episode within the following 2 years (Sadock & Sadock, 2003). This gap in time between the first depressive episode and the first manic episode adds to the difficulty of accurately making this diagnosis in adults. Studies performed by the National Depressive and Manic Depressive Association in 1994 and 2000 both revealed that more than 50% of individuals with bipolar disorder wait 10 years to receive an accurate diagnosis (Hirschfeld et al. 2003; Lish, Dime-Meenan, Whybrow, Price, & Hirschfeld, 1994). Another contributing factor to this problem is a cycle very commonly seen by psychiatrists.

A depressed patient comes in for treatment, is prescribed an antidepressant, and complies with the treatment but notices that she is beginning to feel very happy, so she stops taking the medication and stops the follow-up visits. She eventually experiences hypomania or mania episodes, which she views as a normal mood. This state of mood can result in impulsive behaviors, which can lead to legal issues, financial difficulties, relationship issues, and sometimes psychiatric hospitalization. The manic patient soon crashes and becomes very depressed again, at which time she either restarts the antidepressant or comes back to the psychiatrist to complain about the depression, never mentioning the preceding euphoria.

This cycle can continue for years before it is confirmed that the patient has bipolar disorder. In spite of the challenges with adults, the problem is even greater in children and adolescents. Based on the number of children and adolescents discharged from hospitals in the United States, a national hospital database has estimated the prevalence rate to be as high as 7% (Blader & Carlson, 2007). This number is very high compared to the 1%–2% prevalence observed in adults. This discrepancy highlights the difficulty of diagnosing bipolar disorder in children and adolescents as well as in adults. We do know that researchers in child and adolescent psychiatry are investigating this discrepancy. One study examined the presentation of bipolar children and adults during their first admission; very similar presentations exist in spite of the fact that the adolescents' diagnoses varied, ranging from adjustment disorder and disruptive behavior disorder to depressive disorders (Scott-Gurnell, 2008).

Bipolar disorder can be very complicated in that there are various classifications and presentations. Bipolar type 1 presents as the classical episodic depression and mania either with or without psychosis. Patients with bipolar type 2 experience episodes of severe de-

pression and hypomania. Lastly, individuals who do not necessarily cycle but rather experience symptoms of both depression and mania simultaneously are diagnosed as having bipolar mixed.

Regarding the treatment of bipolar disorder, pharmacology is a major and necessary intervention; however, psychotherapy and education are necessary as well in order to ensure treatment success.

Mood stabilizers, including lithium (see Table 23.2); certain anti-epileptic agents; and antipsychotic agents (see Table 23.3a and Table 23.3b) are very commonly used to treat bipolar disorder. There are also times when adjuvant antidepressants (see Table 23.1) and/or anxiolytics (see Table 23.7) are utilized along with mood stabilizers.

PSYCHOPHARMACOLOGICAL APPROACH TO SLEEP DISORDERS

Several psychiatric disorders have clinical manifestations of disordered sleep onset and maintenance. Primary sleep disorders are categorized as either dyssomnias or parasomnias (American Psychiatric Association, 2000). In sleep disorders in the dyssomnia category, the abnormalities are in the amount, initiation, and/or quality and timing of sleep (see Table 23.4). Examples of dyssomnias are primary insomnia, narcolepsy, sleep apnea, and circadian rhythm sleep disorder. In contradistinction, parasomnias are due to aberrancies in the physiological systems that occur during sleep. Parasomnias include sleepwalking, night terrors, nightmare disorder, and REM sleep behavior disorder (see Table 23.4).

An accurate diagnostic evaluation of an individual presenting with a sleep disorders is multifaceted and is essential for adequate treatment. Historical input from the individual and often collateral input from family members and primary care physicians are important components of this evaluation and allow the clinician to ascertain if a psychiatric and/or medical condition is the underlying etiology of the sleep disturbance (Bourgeois, Hales, & Yudofsky, 2007). Medically ill patients, those with pain disorders, and those with a variety of psychiatric disorders frequently have associated insomnia (Dorrepal, Aaronson, & van Dann, 1989; Gislason & Almqvist, 1987; McCrae & Lichstein, 2002; Rosenberg, 2006; Strang, 1992).

Within the field of sleep medicine, polysomnography is the principal diagnostic tool (Neylan, Reynolds, & Kupfer, 2007). Other diagnostic instruments can be useful, depending upon the clinical presentation (see Table 23.6).

MECHANISM OF ACTION	BRAND NAME/ GENERIC NAME	DOSE RANGE AND DOSE FORMS	SIDE EFFECTS	INDICATIONS
Blocks voltage-sensitive sodium channels by an unknown mechanism Increases brain concentrations of gamma-aminobutyric acid by way of an unknown mechanism	Depakote, Depacon, Depakene, Depakote ER/ valproate, divalproex sodium, valproic acid	Mania: 1200–1500 mg/day Tablet (delayed-release Depakote): 125 mg, 250 mg, 500 mg Tablet (extended-release Depakote ER): 250 mg, 500 mg Capsule (valproic acid Depakene): 250 mg Injection (Depacon): 100 mg/ml Syrup (sodium valproate-Depakene): 250 mg/5 ml	Sedation, tremor, dizziness, ataxia, asthenia, headache, abdominal pain, nausea, vomiting, diarrhea, reduced appetite, constipation, dyspepsia, weight gain, alopecia <i>Controversial effects:</i> Hyperandrogenism, hyperinsulinemia, lipid dysregulation Polycystic ovaries Decreased bone mineral density <i>Life threatening:</i> Rare hepatotoxicity with liver failure, sometimes severe and fatal, specifically among children under 2 Rare pancreatitis, sometimes fatal	Acute mania (divalproex) and mixed episodes (divalproex/divalproex ER) Complex partial seizures that occur either in isolation or in association with other types of seizures (monotherapy and adjunctive)
Blocks voltage-sensitive sodium channels Interacts with the open channel of voltage-sensitive sodium channels Interacts at a specific site of the alpha pore forming subunit of the	Carbatrol, Equetro, Tegretol/carbamazepine	400–1,200 mg/day Under age 6: 10–20 mg/kg/day Chewable tablet: 100 mg, 200 mg Tablet: 200 mg Extended-release tablet: 100 mg, 200 mg, 400 mg	Sedation, dizziness, confusion, unsteadiness, headache, nausea, vomiting, diarrhea, blurred vision, benign leucopenia (transient in up to 10% of patients), Rash <i>Life-threatening side effects:</i> Rare aplastic anemia, agranulocytosis (unusual	Partial seizures with complex symptoms Generalized tonic-clonic (grand mal) seizures Mixed seizure patterns Pain associated with true trigeminal neuralgia Acute mania/mixed mania (Equetro) Glossopharyngeal neuralgia

(continued)

MECHANISM OF ACTION	BRAND NAME/GENERIC NAME	DOSE RANGE AND DOSE FORMS	SIDE EFFECTS	INDICATIONS
voltage-sensitive sodium channel Blocks release of glutamate		Extended-release capsule: 100 mg, 200 mg, 300 mg Oral suspension 100mg/5 ml	bleeding, bruising, mouth sores, infections, fever, sore throat) Rare severe dermatologic reactions (Stevens Johnsons syndrome) Rare cardiac problems Rare induction of psychosis or mania SIADH (syndrome of inappropriate antidiuretic hormone secretion) with hyponatremia Increased frequency of generalized convulsions (in patients with atypical absence seizures)	Bipolar depression Bipolar maintenance Psychosis, schizophrenia (adjuvant)
Unknown and complex Alters sodium transport across neurons and muscle cells. May work through second messenger systems to alter intracellular activity Inhibits inositol monophosphatase Reduces protein kinase C activity Increases cytoprotective proteins and increases gray matter content	Eskalith, Eskalith CR, Lithobid slow release, Lithostat tablets, Lithium carbonate tablets, Lithium citrate syrup/lithium	1,800 mg/day (acute mania) 900–1,200 mg/day in divided doses (maintenance) Liquid: 10 ml 3 times/day (acute), 5 ml 3–4 times/day (long-term) Tablet: 300 mg (slow release), 450 mg (controlled release) Capsule: 150 mg, 300 mg, 600 mg Liquid: 8mEq/5 ml	Ataxia, dysarthria, delirium, tremor, memory problems, polyuria, polydipsia (nephrogenic diabetes insipidus), diarrhea, nausea, weight gain, euthyroid goiter or hypothyroid goiter, possibly with increased TSH and reduced thyroxin levels, acne, rash, alopecia, leukocytosis, side effects are typically dose related <i>Life-threatening side effects:</i> Lithium toxicity Renal impairment (interstitial nephritis) Nephrogenic diabetes insipidus, arrhythmia, cardiovascular changes, sick	Manic episodes of manic depressive illness Maintenance treatment for manic depressive patients with a history of mania Bipolar depression Major depression disorder (adjuvant) Vascular headaches Neutropenia

			sinus syndrome, bradycardia, hypotension, T wave flattening and inversion, rare psuedotumor cerebri, rare seizures	
Block voltage-sensitive sodium channels Interacts with open channels of voltage-sensitive sodium channels Block release of glutamate and aspartate	Lamictal/lamotrigine	100–200 mg/day (monotherapy for bipolar) 100 mg/day with Depakote 400 mg/day with enzyme inducing medications such as Tegretol Pediatric patients 2–12 years old dose per body weight and concomitant medications Scored tablets: 25 mg, 100 mg, 150 mg, 200 mg Chewable tablets: 2 mg, 5 mg, 25 mg	Benign rash (10%), sedation, blurred or double vision, dizziness, ataxia, headache, tremor, insomnia, poor coordination, fatigue, insomnia, poor coordination, fatigue, nausea, vomiting, dyspepsia, abdominal pain, constipation, rhinitis, <i>Additional effects in pediatric patients with epilepsy:</i> infection, pharyngitis, asthenia	Maintenance treatment of bipolar I disorder Partial seizures (adjunctive; adults and children over age 2) Generalized seizures of Lennox-Gestaut syndrome (adjunctive; adults and children over age 2) Conversion to monotherapy in adults with partial seizures who are receiving treatment with Tegretol, dilantin, phenobarbital, primidone or valproate Bipolar depression Bipolar mania (adjuvant and 2nd line) Psychosis, schizophrenia (adjuvant) Neuropathic pain/ chronic pain Major depressive disorder (adjuvant) Other seizure types and as initial monotherapy for epilepsy
Blocks voltage-sensitive sodium channels Interacts with the open channel of voltage-sensitive sodium channels	Trileptal/oxycarbamazipine	1,200–2,400 mg/day Tablet: 150 mg, 300 mg, 600 mg Liquid: 300 mg/5 ml	Sedation, dizziness, confusion, unsteadiness, headache, nausea, vomiting, diarrhea, blurred vision, benign leucopenia (transient in up to 10% of patients), rash	Partial seizures in adults with epilepsy Partial seizures in children and adolescents from 4 to 16 with epilepsy Bipolar disorder

Interactions at a myriad of neurotransmitter receptors

Specific antagonist actions at 5HT2C receptors for cognition and affective symptoms

5HT2C antagonist along with serotonin reuptake blockade of fluoxetine with Symbrax

Oral disintegrating tablet:
5 mg, 10 mg, 15 mg, 20 mg

IM: 5 mg/ml,

Symbyax capsule olanzapine/fluoxetine:
6 mg/25 mg, 6 mg/50 mg, 12 mg/25 mg, 12 mg/50 mg

Rare TD

Rare rash with exposure to sunlight

Life threatening:

Hyperglycemia with ketoacidosis and hyperosmolar coma or death has been reported with 2nd generation antipsychotics, NMS, seizures, increased risk of death and CV events in elderly patients with dementia related psychosis

Bipolar depression in combination with fluoxetine (Symbrax)

Other psychotic disorders

Unipolar depression unresponsive to antidepressants

Behavioral disturbances in children and adolescents

Dementia

Disorders with impulsivity

Borderline personality disorder

23.4

Dyssomnia Pharmacotherapy Treatment Options

TYPE OF DYSSOMNIA	MEDICATION	MECHANISM OF ACTION	MECHANISM OF ACTION
Insomnia	FDA-approved Hypnotic agents		
	Benzodiazepines: Flurazepam Temazepam Estazolam Quazepam Triazolam	Bind to the type 1 and 2 benzodiazepine receptors with varying selectivity and with different pharmacokinetic properties. Quazepam binds only to type 1. However, quazepam’s metabolite binds to both in the central nervous system.	Sedation, ataxia, anterograde amnesia, nausea, slurred speech, rebound insomnia, impaired cognitive and psychomotor function, abuse, dependence potential
	Nonbenzodiazepines: Zolpidem Zaleplon Eszopiclone	Zolpidem, Zaleplon and Eszopiclone bind to the type 1 benzodiazepine receptor.	Due to lack of activity at the type 2 and 3 benzodiazepine receptors, no muscle relaxing or anticonvulsant properties and/or adverse effects; less abuse potential, may cause euphoria; drowsiness, dizziness, and less commonly ataxia, slurred speech; withdrawal symptoms can occur
	Ramelteon	Ramelteon is a melatonin agonist at the MT1 and MT2 receptor that acts in the suprachiasmatic nucleus to regulate sleep-wake cycle. It is reported not to be as effective as other FDA-approved hypnotics.	Headache, somnolence, fatigue, dizziness; meals high in fat can decrease absorption; levels may be increased by fluvoxamine and carbamazepine (cytochrome P450 3A4)
	Chloral hydrate (nonbarbiturate hypnotic)	Efficacy reportedly not as robust as ramelteon; excreted by pineal gland naturally during sleep; maintains sleep-wake cycle acting at the suprachiasmatic nucleus; elderly with insomnia due to lower levels of melatonin	Low margin of safety (lethal dose is approximately 10 times the hypnotic dose); gastrointestinal irritation
	Non-FDA-approved hypnotic agents:	Antihistaminergic effects	
	Melatonin (over the counter)	Heterocyclic antidepressant	
	Off-label uses:	5HT2 receptor antagonist and has antihistaminergic effects	

23.4

Dyssomnia Pharmacotherapy Treatment Options (*continued*)

TYPE OF DYSSOMNIA	MEDICATION	MECHANISM OF ACTION	MECHANISM OF ACTION
	Tricyclic antidepressants (Doxepin, amitriptyline, trimipramine)	Gamma-aminobutyric acid analogues	
	Trazadone	Histamine receptor antagonism	
	Mirtazepine	Binds to Gamma-aminobutyric receptor	
	Gabapentin and Pregabalin		
	Antihistamines (Hydroxyzine, diphenhydramine, promethazine, doxylamine)		
	Valerian extract		
HYPERMOMNIA			
Narcolepsy	Modafinil/Provigil	Increase neuronal activity in hypothalamus	Headache, anxiety, insomnia, dry mouth, diarrhea, nausea, anorexia, hypertension, palpitations, transient EKG ischemic changes
	Armodafinil		
	Sodium Oxybate		
	Psychostimulants	See table 23.9	See table 23.9
CRSD			
Shift work disorder	Melatonin (evidence is not conclusive regarding efficacy)		
	Hypnotics (increase sleep time; however, unclear if nighttime alertness improves)		
	Modafinil (FDA approved for this indication)		
	Caffeine improves alertness		

(continued)

23.4

Dyssomnia Pharmacotherapy Treatment Options *(continued)*

TYPE OF DYSSOMNIA	MEDICATION	MECHANISM OF ACTION	MECHANISM OF ACTION
Jet lag disorder	Methamphetamine improved alertness		
	Melatonin with some evidence to suggest efficacy		
	Hypnotic agents (effects on daytime symptoms unclear)		
Advanced sleep phase disorder	Slow release caffeine with some evidence to support improved alertness		
	Melatonin data not sufficient		
Delayed sleep phase disorder	Effective agents: Melatonin Vitamin B12		
	Non-effective: Hypnotic agents Psychostimulant agents		
Free-running disorder (rare in sighted individuals; common in the blind population)	Effective agents: Melatonin Vitamin B12		
	No data available: Hypnotic agents Psychostimulant agents		
Irregular sleep-wake rhythm	Melatonin use non-conclusive evidence		
	Modafinil no published reports		
	Hypnotic agents without sufficient research		
Dyssomnia NOS			
Restless leg syndrome Periodic limb movement disorder	Pramipexole	Dopamine agonist (D2 and D3 receptors)	

23.5

Sleep Disorders

TYPE	DSM IV-TR	SLEEP ABNORMALITY
Dysomnias	Primary insomnia Primary hypersomnia Narcolepsy Breathing-related sleep disorder Circadian rhythm disorders Dyssomnia not otherwise specified Restless leg syndrome Periodic limb movement disorder	Amount, timing, or quality of sleep is abnormal.
Parasomnias	Nightmare disorder Sleep terror disorder Sleep walking disorder Parasomnia not otherwise specified REM sleep behavior disorder Sleep paralysis	Physiological events and behaviors are abnormal within the context of sleep, specific sleep stages, or sleep-wake transitions.
Medical-Psychiatric Disorders	Sleep disorder related to another mental disorder (i.e., mood, anxiety, or psychotic disorder) Sleep disorder due to a general medical disorder Substance-induced sleep disorder	Pathophysiological mechanism responsible for psychiatric disorder affects sleep-wake system. Disruption in sleep is significant and related to pathophysiology of medical disorder. Alteration in sleep patterns is prominent and related to use or discontinuance of a substance or medication.

Melvin and Lewis table 1 modified (p. 627); *DSM IV-TR* (2000).

The clinical management of primary sleep disorders can consist of educational, psychological, pharmacologic, and combined approaches. Insomnia is the most prevalent sleep disorder, chronically affecting 10%–15% of the adult population and up to 35% transiently (Rosenberg, 2006; Roth, 2001). Insomnia is differentiated by sleep onset versus sleep maintenance.

Sleep maintenance problems are most common in specific diagnostic categories and patient populations. Elderly individuals and perimenopausal women are the demographic groups most commonly affected (Foley, Monjan, Brown, Simonsick, Wallace, & Blazer, 1995; McCall, 1995; Moe, 1999; Reynolds, 1996; Rosenberg, 2006; Webb, 1982).

Psychoeducational strategies have been employed to inform individuals about normal sleep and routines that promote sleep onset and maintenance; however,

these strategies are most effective when used in combination with other treatment options (Chesson et al., 1999; Neylan et al., 2007). An individual's motivation is key when nonpharmacological treatments such as psychotherapy techniques that include hypnosis, progressive muscle relaxation, meditation, and deep breathing are being used (Neylan et al., 2007). The literature has reported that both medication and combined therapy have positive short-term effects on chronic insomnia compared to placebo; however, cognitive-behavioral therapy has demonstrated a long-term improvement of psychological activity and daytime functioning associated with sleep (Wu, Jinfeng, Chungai, Deng, & Long, 2006). Pharmacological treatment options for insomnia span multiple medication categories, which possess differing mechanisms of action and side effects (see Table 23.4).

23.6

Decision Diagnostic Tree

Medical history to rule out sleep disorder related to medical condition

Psychiatric history to rule out secondary sleep disorder

Sleep history

Developmental factors

Collateral reports

Sleep log/journal

Additional testing or supplemental tests

Polysomnography

Child Sleep Habits Questionnaire

Pediatric Sleep Questionnaire

Morningness-Eveningness Questionnaire

Circadian phase markers

Multiple Sleep Latency test

Stanford sleepiness scale

Maintenance of wakefulness test

From *Board Prep and Review Guide for Psychiatry*, by J.A. Bourgeois, R.E. Hales, & S.C. Yudofsky, 2007. Washington, DC: American Psychiatric Publishing; "Guidelines for the Multiple Sleep Latency Test (MSLT): A Standard Measure of Sleepiness," by M.A. Carskadon, W.C. Dement, M.M. Mitler, T. Roth, P.R. Westbrook, & S. Keenan, 1986. *Sleep*, 9, 519–524; "Quantification of Sleepiness: A New Approach," by E. Hoddes, V.P. Zarcone, H. Smythe, R. Phillips, & W.C. Dement, 1973. *Psychophysiology*, 10, 431–436; and "The Multiple Sleep Latency Test as an Evaluation for Excessive Somnolence," by M.M. Mitler, 1982. In C. Guilleminault (Ed.), *Disorders of Sleeping and Walking: Indications and Techniques* (pp. 145–153). Menlo Park, CA: Addison-Wesley.

Narcolepsy is a dyssomnia that is often the etiology of hypersomnolence. This dyssomnia results in the intrusion of REM sleep into wakefulness. Many agents such as dopaminergic stimulants, tricyclic antidepressants, sodium oxybate, armodafinil, and modafinil have been effectively utilized to improve arousal by different mechanisms of action (Black & Houghton, 2006; Harsh et al., 2006; Stahl, 2006). In addition to pharmacotherapy, scheduled naps during the day can improve wakefulness (Helmus, Rosenthal, Bishop, Roehrs, Syron, & Roth, 1997; Neylan et al., 2007).

When there is misalignment between external demands and biological rhythms, the sleep-wake cycle

can become disrupted, resulting in a circadian rhythm sleep disorder (CRSD). These sleep disorders are the result of physiological, environmental, and maladaptive behavioral factors (Barion & Zee, 2007). Clinical manifestations of CRSDs include hypersomnia or insomnia, which is dependent upon the juxtaposition of performance requirements and the internal circadian timing system (Barion & Zee, 2007). In addition to CRSDs secondary to medical conditions and substance or drug abuse, and a general category of CRSD not otherwise specified, the *International Classification of Sleep Disorders* recognizes six types of CRSDs: (1) delayed sleep phase type, (2) advanced sleep phase type, (3) irregular sleep-wake phase type, (4) free-running type, (5) jet lag type, and (6) shift work type (American Academy of Sleep Medicine, 2005; Sack, Auckley, Auger, Carskadon, Wright, Vitello, & Zhdanova, 2007). The literature describes many assessment strategies. From a research perspective, the phase and the amplitude of the core body temperature and the dim light melatonin onset are strongly correlated as phase markers (Boivin, Duffy, Kronauer, & Szeisler, 1996; Sack et al., 2007; Shanahan & Czeisler, 1991). Sleep logs and diaries, actigraphy, and polysomnography are utilized to clinically evaluate the presence or absence of a CRSD (Czeisler et al., 2005; Morgenthaler et al., 2007; Sack et al., 2007). The efficacy of numerous behavioral, environmental, and pharmacological interventions is described in the literature (see Tables 23.4 and 23.5).

The majority of the parasomnias occur in the pediatric population. Primary parasomnias result in periods of abnormal motor or verbal behavior during sleep arousals (Giglio, Undevia, & Spire, 2005). In the *DSM-IV-TR*, parasomnias are characterized as sleepwalking disorder, sleep terror disorder, nightmare disorders, REM sleep behavior disorder, and sleep talking. Parasomnias are also described as disorders of arousal, including REM sleep behavior disorder, nocturnal seizures, rhythmic movement disorder, and bruxism (Wills & Garcia, 2002).

The most common form of primary parasomnia is disorders of arousal. The clinician can diagnose this by gathering historical information from the patient and family; polysomnography can assist with excluding sleep terrors and seizure disorders (Giglio et al., 2005). The pathophysiological mechanisms of parasomnias are not known. Vecchierini (2001) describes the management of parasomnias as dependent upon the patient's age, the frequency and intensity of the episodes, the familial structure, the presence of precipitating and risk factors, psychological factors, and the specific type of parasomnia. Treatment modalities include reassurance and psychoeducation, encouragement of regular sleep

patterns and avoidance of drugs and alcohol, protective strategies to avoid injury, behavioral psychotherapy, and pharmacotherapy, when indicated. Confusional arousals and sleepwalking may respond to short trials of low-dose benzodiazepines (Giglio et al., 2005). Sleep terrors and rhythmic movement disorder have been treated with benzodiazepines and tricyclic antidepressants with efficacy (Giglio et al., 2005). Sleep bruxism has been managed pharmacologically through the use of antipsychotic and antidepressant medications (Amir, Hermesh, & Gavish, 1997; Giglio et al., 2005; Por, Wastson, Doucette, & Dolovich, 1996). Case reports and small patient series have described the use of beta-blockers and botulinum toxin in the treatment of sleep bruxism (Amir et al., 1997; Giglio et al., 2005; Tan & Jankovic, 2000). The treatment of secondary sleep disorders associated with psychiatric disorders will be addressed in the discussion of specific diagnostic categories.

PSYCHOPHARMACOLOGICAL APPROACH TO ANXIETY DISORDERS

Anxiety disorders are among the most prevalent psychiatric disturbances, with a lifetime prevalence of 28.8% (Kessler et al., 2005). The *DSM-IV-TR* describes 12 distinct categories: panic disorder with and without agoraphobia, agoraphobia without history of panic disorder, specific phobia, social phobia, obsessive-compulsive disorder, post-traumatic stress disorder, acute stress disorder, generalized anxiety disorder, anxiety disorder due to a general medical condition, substance-induced anxiety disorder, and anxiety disorder not otherwise specified (American Psychiatric Association, 2000). Because of the pervasiveness of these disorders, many people never seek mental health treatment for their anxiety symptoms. That is, because anxiety presents as “fear” or “nervousness” many people do not recognize the symptoms as pathological, and thus do not seek mental health treatment. Although individuals may be impaired in their daily functioning, they may not present for treatment until their symptoms are protracted and severely debilitating. Psychosocial treatment modalities have evidence to support their clinical utility. Cognitive-behavioral therapy, exposure and response prevention, and systematic desensitization are effective in the treatment of various anxiety disorders (American Psychiatric Association, 2004a). In extreme clinical circumstances, electroconvulsive therapy and psychosurgery have been utilized to provide symptomatic relief for patients with obsessive-compulsive disorder (American Psychiatric Association, 2004a).

Pharmacotherapy options include medications that are FDA approved for specific anxiety disorders, medications that are used off-label, and herbs and supplements that are not FDA approved (Stahl, 2006). Barbiturates and benzodiazepines are two classes of agents that have been used historically to treat anxiety and insomnia. Antihistamines, noradrenergic medications, various categories of antidepressants, atypical antipsychotic agents, anticonvulsants, and aspirin have all been utilized to treat anxiety (see Table 23.7). The mechanisms of action of these medications range from increasing GABA (benzodiazepines) and serotonin levels to blocking central or peripheral noradrenergic activity (see Table 23.8).

The practicalities of treating anxiety disorders often necessitate the use of a benzodiazepine in the short term, while antidepressants and other medications, along with psychosocial therapies, have a longer onset of action. The FDA guidelines give specific approval of the use of certain benzodiazepines, selective serotonin reuptake inhibitors, and selective serotonin and norepinephrine reuptake inhibitors in particular anxiety conditions, and it is posited by many in the psychiatric literature that they are all efficacious in treating the array of anxiety disorders (Schatzberg, Cole, & deBattista, 2007). Strategies to incorporate while prescribing include being attuned to patient symptoms, gathering personal and family psychiatric and substance abuse or dependence history, ascertaining the patient's preferences, and explaining potential adverse effects. It is important to discuss the FDA warnings of abuse, dependence for benzodiazepines, risk of increased suicidal ideation and behavior with all antidepressants, and risk of liver failure associated with nefazodone when one is presenting pharmacologic treatment options. Engaging patients and families in conversation regarding your rationale for treatment with a specific agent, including information about off-label uses, potential adverse events, and expected time course of treatment, is essential to strengthen the therapeutic alliance, treatment adherence, and optimal outcomes. Ongoing psychoeducation about the psychiatric disorder and exploration of treatment possibilities are both key to favorable results.

PHARMACOLOGICAL APPROACHES TO PSYCHOTIC DISORDERS

Psychotic disturbances are classified as a specific symptom cluster of positive and negative symptoms that are found across a variety of psychiatric conditions. The lifetime prevalence of any psychotic disorder ranges

23.7

Anxiety Disorders and Psychopharmacological Options

PSYCHIATRIC DISORDER	GENERALIZED ANXIETY DISORDER	OBSESSIVE- COMPULSIVE DISORDER	SOCIAL PHOBIA	POSTTRAUMATIC STRESS DISORDER	PANIC DISORDER
FDA medication options	Alprazolam, Paroxetine, Escitalopram, Duloxetine, Venlafaxine	Clomipramine, Fluvoxamine and Fluoxetine for children, adolescents and adults; Paroxetine and Sertraline	Paroxetine, Sertraline, Fluvoxamine, Venlafaxine	Paroxetine, Sertraline	Alprazolam, Clonazepam, Fluoxetine in children, adolescents and adults; Paroxetine, Sertraline and Venlafaxine
Monitoring/ Adverse Side Effects	Alprazolam long term include risk of dependency Sedation, fatigue, depression, dizziness, ataxia, slurred speech, forgetfulness, respiatory depression See table 23.1	See table 23.1	See table 23.1	See table 23.1	Clonazepam sedation, fatigue, depression, slurred speech, ataxia, forgetfulness, rare hallucinations, respiatory depression

American Physician Institute for Advanced Professional Studies, LLC, 2007.

from 3.06% to 3.48%, with schizophrenia ranging from 0.87% to 1.5% (American Psychiatric Association, 2000; Perala et al., 2007). According to the *DSM-IV-TR*, “the term *psychotic* refers to delusions, any prominent hallucinations, disorganized speech, or disorganized or catatonic behavior” (American Psychiatric Association, 2000, p. 273). These symptoms are found in brief psychotic disorder, schizophreniform disorder, schizophrenia, schizoaffective disorder, and delusional disorders. Psychotic symptoms may also occur over the clinical course of bipolar disorder, depressive disorder, delirium, dementia disorders, certain personality disorders, and substance-related disorders, and with general medical conditions.

Given the complexity of symptom presentation and the safety concerns that individuals with psychosis pose, an evaluation conducted in a safe and structured environment is optimal. Psychiatric management is divided into three phases (American Psychiatric Association,

2004b). In the acute phase, the assessment entails collection of data regarding positive and negative symptom history and evaluation for potential comorbid psychiatric disorders (depression, substance-related disorders, post-traumatic stress disorder, etc.) and for concurrent general medical conditions. Along with gathering history from the patient and collateral sources, serial mental status examinations are very helpful in assisting with the delineation of symptoms to narrow the differential diagnosis. The utilization of psychometric instruments and rating scales such as the Structured Clinical Interview for *DSM-IV* (First, Spitzer, Gibbon, & Williams, 1995), the Brief Psychiatric Rating Scale (Overall & Gorham, 1962), the Positive and Negative Syndrome Scale (Kay, Fiszbein, & Opler, 1987), and the Abnormal Involuntary Movement Scale (Munetz & Benjamin, 1988) are also beneficial from a clinical standpoint to assess progress and to monitor adverse effects. Psychoeducation is provided for the patient and family in this acute phase,

	BENZODIAZEPINES	ANTIDEPRESSANTS	AZAPRIONES	ANTICONVULSANTS	NORADRENERGIC
Mechanism of Action	GABA receptor activity 3 Subclasses	Selective serotonin reuptake inhibitors Selective serotonin-norepinephrine reuptake inhibitors Tricyclics Heterocyclics	Buspirone (partial agonist of the 5-HT _{1A} receptor; does not bind with high affinity to GABA and benzodiazepine receptors; GAD takes 2–4 weeks for efficacy)	Gabapentin (Alpha ₂ X subunit of calcium channel in CNS; social anxiety, GAD, panic) Tiagabine (selectively inhibits GABA reuptake and the GAT1 GABA transporter; GAD, PTSD, panic) Pregabalin (analogue of GABA and acts more selectively than Gabapentin at the Alpha ₂ X subunit of calcium channel in CNS; GAD FDA approval pending)	Beta-blockers: propranolol, atenolol (relieves akathisia and somatic symptoms of anxiety) Alpha ₂ receptor agonists: clonidine, guanfacine (pre- and postsynaptic receptor activity)
Dosing Guidelines	Alprazolam 1–6 mg in divided doses Clonazepam 0.5–2 mg/day divided or nightly doses	See table 23.1	Buspirone 5 mg bid and increased to 30–60 mg/day	Gabapentin 900–1,800 mg/day in 3 divided doses 2–12 mg/day for adjuvant treatment of anxiety	Propanolol 10 mg TID See table 23.9 for clonidine and guanfacine
From <i>Manual of Clinical Psychopharmacology</i> (6th ed.), by A. F. Schatzberg, J. O. Cole, & C. deBattista, 2007. Arlington, VA: American Psychiatric Publishing; and <i>Essential Psychopharmacology: The Prescriber's Guide Revised and Updated Edition</i> , by Stephen Stahl, 2006, New York: Cambridge University Press.					

along with reassurance. Individuals who are actively psychotic can benefit from supportive psychotherapy. Many evidence-based pharmacotherapy options for the acute phase are reported in the literature. Antipsychotic medications, anxiolytics, mood stabilizers, and beta-blockers are used to address psychosis, potential agitation, and aggression. In this initial phase of treatment, injectable and dissolvable formulations of typical and atypical antipsychotic agents are often utilized, while oral forms of antipsychotic medications are administered for longer-term treatment. The efficacy of antipsychotic agents is 75% of initial responders after a 6-week trial versus 25% placebo. Approximately 30% of those who do not experience improvements with standard antipsychotic agents benefit from clozapine (Meltzer, 1997; Meltzer, Bastani, Kwon, Ramirez, Burnett, & Sharpe, 1989; Schatzberg et al., 2007; see Table 23.3b). Individuals with schizophrenia are at increased risk for suicide attempts and completed suicides in comparison to the general population (American Psychiatric Association, 2004b). As such, individuals should be evaluated and treated in the acute phase with suicide precautions and close observation, if indicated. With adequate pharmacotherapy in this phase of treatment, it is expected that psychotic symptoms should decrease within 2–4 weeks (American Psychiatric Association, 2004b).

Once an individual's symptoms have abated and/or he or she clinically returns to baseline, the treatment enters the stabilization phase. During this phase of treatment, safety is less of a concern, since the patient's reality testing has improved substantially. The oral formulations of antipsychotic agents are primarily used in this phase of care. If comorbid psychiatric disorders are present, additional psychotropic medications are prescribed (refer to specific sections of this chapter to address comorbid conditions). Clinicians continue to monitor symptoms while attempting to diminish psychosocial stressors, increase available social supports, and improve daily function and adaptation for their patients.

The acute and stabilization phases last approximately 6 months in total. By comparison, the stable treatment phase is prolonged and sometimes lasts throughout the individual's lifetime. The rate of relapse for psychotic disorders is very high. One study followed individuals who presented with an acute psychotic disorder. After remission of symptoms for 6 months, they were assigned to either guided discontinuation of antipsychotic medications with small dose reductions or continued maintenance of atypical antipsychotic agents. There was a relapse rate of 21% in the group treated with medication, and 43% in the group with the grad-

ual discontinuation of medication (Wunderink, Nienhuis, Sytema, Slooff, Knegtering, & Wiersma, 2007). These and other findings have underscored the importance of ongoing pharmacologic treatment for the majority of psychotic-related disorders. The American Psychiatric Association (2004b) practice guidelines recommend indefinite maintenance treatment if there is a clinical history of "multiple prior episodes or two within a five year time period" (p. 13). Within the context of the stable treatment phase, the goals are to promote function and recovery. Rates of deterioration in clinical status are much higher with discontinuance of antipsychotic agents in the first 3 months of treatment than with prudent tapering of agents (Baldessarini & Viguera, 1995; Schatzberg et al., 2007). The clinician must weigh the risks versus benefits when considering tapering antipsychotic medications and/or dose reduction and communicate his or her thoughts and concerns to the patient and/or responsible party. If there are concerns regarding non-adherence to pharmacologic treatment, long-acting depot haloperidol, fluphenazine, and risperdal are viable treatment options. Lower doses of haloperidol depot are better tolerated with respect to extrapyramidal side effects than oral Haldol; however, they are associated with higher relapse rates (Schatzberg et al., 2007).

Since the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) schizophrenia trial was conducted (Lieberman et al., 2005), the superior efficacy of second-generation antipsychotic medications over first-generation antipsychotics has been called into question. Comparisons of olanzapine, risperidone, quetiapine, ziprasidone, and perphenazine from the CATIE trial revealed that olanzapine demonstrated only a slightly improved efficacy. The typical and atypical antipsychotic medications all yielded improvements in cognition. Perphenazine demonstrated similar efficacy to and lower cost than the second-generation antipsychotics, as well as a modest increase in motor adverse effects. Given the brevity of this trial, there is debate in the literature regarding clinical utility over the long term and concerns of increased rates of extrapyramidal side effects (Swartz et al., 2008). In phase 2 of CATIE, clozapine was compared to olanzapine, risperidone, and quetiapine and showed greater efficacy in treatment-resistant patients (McEvoy et al., 2006). Atypical antipsychotic medications are favored by prescribers based upon decreased risk of the development of extrapyramidal symptoms, improved negative symptoms related to decreased extrapyramidal symptoms, and improved mood symptoms due to action at the serotonin and dopamine receptors. These distinctions improve tolerabil-

ity and adherence to treatment. With the advantages of second-generation antipsychotic agents, there are also disadvantages: cost, metabolic syndrome, cerebrovascular risks in the elderly, and potential for prolonged QTc (the time needed for the heart to recover from the previous heart beat). The FDA issued warnings covering all atypical antipsychotic medications concerning “enhanced risk of hyperglycemia and diabetes” in 2003, and “risk of increased cerebrovascular adverse events in elderly populations based on increased rates in some studies of use with olanzapine and risperidone” in 2005 (Leigh-Pemberton, von Moltke, & Greenblatt, 2006; Rosack, 2005; Schatzberg et al., 2007). The risk of stroke in elderly patients using atypical antipsychotic agents has since been refuted by analysis of a large community geriatric sample (Hermann, Mandani, & Lanctot, 2004; Schatzberg et al., 2007). Not only do prescribers need to keep current with data on efficacy and the adverse effects of treatment, but they also need to balance costs and benefits, including medical and psychological well-being. Selecting an antipsychotic agent that has the best efficacy with limited costs and side effects that are not likely to perpetuate or precipitate medical conditions, given the individual’s history and/or genetic predisposition, is an example of the art of psychopharmacology. Numerous practice parameters and clinical guidelines have been proposed, and key features are summarized in the Tables 23.3a and 23.3b.

PSYCHOPHARMACOLOGICAL APPROACHES TO ATTENTION-DEFICIT/ HYPERACTIVITY DISORDER

Attention-deficit/hyperactivity disorder is a very controversial disorder that has been historically referred to as “minimal brain dysfunction/damage,” “hyperkinetic reaction,” and “hyperkinesis.” The name has changed along with the criteria since the publication of the first edition of the *DSM*. ADHD is the name currently used, with the type specified as either inattentive, hyperactive/impulsive, combined, or not otherwise specified. The term ADHD will be all inclusive during this discussion.

ADHD is diagnosed by clinical interview, since there is no test for ADHD (American Academy of Child Psychiatry, 1997). Although psychological testing is often done to delineate more accurately the specific deficits and to help rule out comorbidity, it is not definitively used for diagnostic purposes. Numerous scales are used as diagnostic scales and to monitor response to medication, but the most common

are the Child Behavior Checklist (Achenbach, 1991; Biederman et al., 1993), the Teacher Report Form of the Child Behavior Checklist (Achenbach, 1991; Edelbrock, Costello, & Kessler, 1984), and the Conners’ Parent and Teacher Rating Scales (Conners et al., 1969; Goyette, Conners, & Ulrich, 1978). These scales and many others are used to support the diagnosis as well as to monitor the progress and success of treatment interventions. According to the *DSM-IV-TR*, the clinical interview of the patient, whether adult or child with guardian/caretaker, should be thorough enough to provide the data needed to confirm the diagnosis. There are three areas of symptoms to be explored, as listed by the *DSM-IV-TR*. Inattentiveness, which manifests as being unable to attend closely to details, making careless mistakes, having difficulty sustaining attention, not listening, not completing tasks, having poor organization skills, avoiding activities requiring sustained mental effort, losing things, being forgetful, and being easily distracted. Hyperactivity involves fidgeting, being out of one’s seat in the classroom without permission, running or climbing excessively, having difficulty playing quietly, talking excessively, and moving as if “driven by a motor.” Impulsivity involves blurting out answers, having difficulty waiting, and being intrusive with others. Symptoms must be present for 6 months and have existed since the age of 7 years. Thus, getting academic functioning history from adults is crucial during the assessment. In addition to the above criteria, functional impairment in at least two settings, such as a social, academic, or occupational setting, must be present (American Psychiatric Association, 2000). Inattentive type of ADHD is the most difficult to diagnose and is often missed. This type is more common in girls, and in evaluation, it is important to assess for excessive daydreaming, which sometimes causes the individual to lose chunks of time. These individuals are not very talkative and have difficulty completing tasks and organizing so as to keep up with their assignments. As adults, they often miss deadlines and have great difficulty with time management skills. Interviewing spouses and gathering information from teachers can produce very helpful collateral data to support the diagnosis. Although most adults do not exhibit excessive motoric hyperactivity, they admit to fidgeting, chewing on pens or pencils, or thumping their desk continuously to help them stay on task.

ADHD affects 3%–7% of school-age children (American Psychiatric Association, 1997b; Sadock & Sadock, 2003). Many studies have reported prevalence rates between 3.3% and 6.5% in girls and 5.8% and

17.1% in boys 4–17 years old (Cohen et al., 1993; Szatmari, Offord, & Boyle, 1989). There is consistency in the ratio of boys to girls of 4:1 (American Psychiatric Association, 1997b). Thirty to eighty percent of individuals diagnosed with ADHD as children continue to meet criteria for the disorder as adolescents, and 65% into adulthood (Barkley, 1996; Weiss & Hechtman, 1993). Weiss and Hechtman reported that 30%–70% of adults who had ADHD as children admit to having at least one core ADHD symptom in adulthood. ADHD is thought to affect 1%–6% of adults (Sankaranarayanan, Puumala, & Kratochvil, 2006). A clinical example to support this finding involves a situation that is seen time and time again.

Mr. T is a 33-year-old fireman who reports having had treatment for ADHD in the past. He has not required medications since he left college almost 10 years ago. He has been able to function as a fireman, husband, and father without much difficulty. He now requests treatment because he was promoted to arson investigator. His new position requires attention to detail and timely reports, which led him to seek treatment again. Mr. T complains of daydreaming, doodling, and constantly fidgeting when trying to get his reports completed. He enjoys going to the scenes but states that he often forgets details of his procedures, such as labeling everything appropriately and making copies of all documents before submitting them. He states that he is easily distracted by the noisy office where he and many others have cubicles. Mr. T is eating and sleeping well and denies any symptoms of depression. His prior medication was Ritalin, but he states that he stopped taking it because he felt it changed his personality when he first started as a fireman—that is, he was too quiet. His son is currently treated for ADHD with Adderall XR and he agrees to take the same. After 3 months at the new position, Mr. T chooses to step down and return to his prior assignment as a fireman. He reports that the hassle of getting the reports done, even with the medication, has been overwhelming and intolerable. His avoidance of difficult tasks, leading to procrastination as well as distractibility, daydreaming and doodling, hyperactivity (fidgetiness), and poor organization are all residual symptoms of ADHD, which have prevented Mr. T from succeeding at his new position. Before returning to his original position, he tries Strattera but finally admits he just does not want to take any medications on a daily basis and does not want the hassle of the investigator position.

Despite the suffering of so many patients with ADHD, the mere existence of ADHD remains controversial. Years of research support the genetic familial

predisposition, with a higher concordance rate among monozygotic twins than among dizygotic twins (Sadock & Sadock, 2003). Parents of children with the disorder often have the same symptoms as their children. The choice to treat is also greatly supported by the negative prognostic factors of untreated children, who experience a higher rate of substance abuse and delinquent behaviors. Adults without treatment tend to be of low socioeconomic status, have difficulty maintaining employment and poorer parenting skills, and experience feelings of demoralization and underachievement (American Psychiatric Association, 1997b).

Treatment of pure ADHD without any comorbidity can be very simple. Unfortunately, over 50% of all individuals with ADHD have some form of comorbidity, including learning disorders, mood and anxiety disorders, oppositional defiant disorder, and conduct disorders (American Psychiatric Association, 1997b). Evidence has shown that individual therapy, social skills groups, parenting skills classes, and educational and behavioral interventions all play a very important role in helping these individuals (Sadock & Sadock, 2003). As psychiatrists and mental health providers, we wear many hats and are responsible for serving as advocates for our patients. Psychopharmacological interventions of choice include the stimulant medications, which are one of the most richly studied medications utilized in the field of medicine. Stimulants have a 75%–85% response rate in the treatment of children with ADHD if we include the first and second stimulant prescribed per person (American Psychiatric Association, 1997b; Sadock & Sadock, 2003). Most of the studies of ADHD treatment have been conducted with children and adolescents. More pharmaceutical companies are seeking FDA approval for the treatment of ADHD in adults (see Table 23.9). Once the diagnosis is confirmed, the patient—and family, as appropriate—is educated about ADHD and provided with supportive channels and resources, such as information about and contact information for Children and Adults with Attention Deficit Hyperactivity Disorder, educational alternatives, and treatment options, including medication options. During the evaluation, the clinician has a duty to inquire about the patient's and/or parents' substance abuse history. Stimulants do have a high street value, and no clinician wants to risk supporting this type of activity. If suspected, the clinician can manage this by prescribing long-acting stimulant agents or non-stimulants. It is also important to understand the patient's or parents' attitudes, beliefs, and misconceptions about stimulants. Many parents believe the medication will make their children “zombies” or make them substance abusers. In such cases, it is im-

portant for the prescriber to educate the patient and his or her family. It is always interesting to discuss the effect that stimulants have on someone with ADHD brain chemistry versus someone without ADHD brain chemistry. That is, ADHD individuals do not get stimulated or excited by the orally or transdermally delivered medication. In contradistinction, the opposite reaction of a calming or slowing of the individual occurs. The parent/adult patient should then be reminded that this reaction does not support dependency and that the ADHD patient can take and miss dosages at will without any signs of withdrawal or cravings. We also explain the “zombie” effect as a mere side effect that occurs if the dosage is too high and not only calms the individual but sedates him or her. Families can be reassured that this is not the goal of the treatment or a tolerable side effect. However, if we lower the dose of the medication, the slowing or sedation will subside. Lastly, because of the recent FDA mandated black box warning, we must inquire about any cardiac symptoms or history of the child or the sudden death of a relative before the age of 40. Both are possible indicators of congenital cardiac abnormalities that place the patient at risk of sudden death with stimulant medications. Positive responses to the cardiac line of questions would indicate a need to order an electrocardiogram baseline reading and obtain cardiac clearance from the patient’s pediatrician. Recently, however, the AACAP Presidential Institute of Practical Pediatric Psychopharmacology recommended that every child should have a baseline EKG performed before the initial dose of stimulant medication is prescribed. However the AACAP (American Association of Child and Adolescent Psychiatry) and the APA (American Pediatric Association) continue to review the implications of this recommendation (Madaan, 2008).

Regarding stimulants, there are two basic types utilized in the treatment of ADHD: methylphenidates and amphetamines, single and mixed compounds (see Table 23.9). Very often, by the time individuals come to psychiatrists for treatment, they are desperate and at risk of either losing their jobs or being expelled from school. The urgency of the situation offers a prime opportunity for stimulant intervention and treatment. A quick warning here: avoid utilizing stimulants to confirm a diagnosis of ADHD, and never treat a patient with a stimulant unless you are 100% sure that the patient has ADHD. The convenience for patients in using stimulants is how quickly they are effective and patients do not need to reach a steady state to see the results. Thus, in treating patients, a rule of thumb is “Start low and go slow,” whether you are using the single isomer (short acting) or the dual isomer (long acting). It is important

to ask the patient to pay attention to the duration of action in the first 3 days; otherwise, if patients and their teachers notice how fast the medication wears off, they conclude that it is ineffective, when actually titration is the reason. In other words, it is not unusual for parents and teachers to notice the abrupt change in the child’s behavior with the onset of stimulant medication, even if the duration is only 2–4 hours. However, by day 5, after suffering for the last 4–5 hours every day, teachers sum up their entire day by saying the medication does not work. Only when they are questioned specifically about various times of the day can this information become useful. It is also important to discuss side effects with patients and/or families. The side effects are the same for all stimulants (see Table 23.9).

Non-stimulant treatments for ADHD include Strattera, Wellbutrin, and alpha agonists such as Tenex and clonidine. Strattera has been shown to be more effective than placebo in ADHD, and it is often used alone or in combination with low-dose stimulants. There is anecdotal evidence that it is effective with ADHD inattentive type and with ADHD patients who also suffer from anxiety or mood lability (bipolar disorder and mood disorder not otherwise specified). In the latter group, Strattera is beneficial because it does not exacerbate the lability and mood swings in these individuals, as do the stimulants. However, it is very important to understand that Strattera can exacerbate a manic episode in bipolar children if the dosage is too high or if the child cycles into a manic episode. At such time, reducing or discontinuing Strattera can be helpful. Strattera has side effects very similar to those experienced with stimulants, such as loss of appetite, sedation, mood lability, and GI upset or nausea. Nausea and sedation are the most common side effects and require a very slow titration, as tolerated by the individual. Monitoring of liver function while the patient is on Strattera is also important, since there have been reports of elevated liver enzymes and hepatotoxicity. Strattera, unlike stimulants, must be taken daily to reach a steady state and become most efficient. Adherence to the treatment schedule and dose is a must. Strattera is not a federally monitored scheduled medication, and it has no street value like the stimulants; thus refills by telephone can be authorized by the prescribing clinician.

The use of Wellbutrin for the treatment of ADHD has been reported in the literature, but there are no reported double-blind, placebo-controlled studies (Conners et al., 1996). There is anecdotal evidence that it shows promise with inattentive-type ADHD and with individuals who suffer from both ADHD and a mild to moderate depressive episode.

MECHANISM OF ACTION	BRAND NAME/GENERIC NAME	DOSE RANGE AND DOSE FORMS	INDICATIONS	SIDE EFFECTS
Methylphenidate compounds: Increases norepinephrine and dopamine action by blocking reuptake	Focalin, Focalin XR methylphenidate (D)	2.5–20 mg/day Tablet: 2.5 mg, 5 mg, 10 mg XR extended release capsule: 5 mg, 10 mg, 20 mg	ADHD Narcolepsy Treatment-resistant depression	Insomnia, headache, exacerbation of tics, nervousness, irritability, tremor, overstimulation, dizziness, anorexia, nausea, abdominal pain, weight loss, can temporarily slow normal growth in children (controversial), Blurred vision
Enhance norepinephrine and dopamine action in the dorsolateral prefrontal cortex, to improve attention, concentration, executive function and wakefulness	Concerta, Metadate CD, Ritalin, Ritalin LA/ methylphenidate (D, L)	ADHD: up to 2 mg/kg/day in children 6 and older up to 60 mg 20–60 mg in adults Narcolepsy: 20–60 mg in 2–3 doses	ADHD Narcolepsy (Metadate ER, Mehtylin ER, Ritalin, Ritalin SR) Treatment resistant depression	<i>Life-threatening side effects:</i> Psychotic episodes, especially with parental abuse Seizures, palpitations, tachycardia, hypertension, Rare NMS
Enhance dopamine actions in basal ganglia to improve hyperactivity				
Enhance dopamine and NE in medial prefrontal cortex and hypothalamus which likely improves depression, fatigue and sleepiness	Other Methylphenidate compounds: Daytrana patch	Immediate release tablets: 5 mg, 10 mg, 20 mg (Ritalin, methylin) Immediate release chewable tablets: 2.5 mg, 5 mg, 10 mg Oral solution 5 mg/ml, 10 mg/5 ml Older sustain release tablets: 10 mg, 20 mg, (Metadate ER, Methylin ER) 20 mg (Ritalin SR) Newer sustained release capsules: 20 mg, 30 mg, 40 mg, (Ritalin LA) 10 mg, 20 mg, 30 mg (Metadate CD)		Rare activation of hypomania, mania, or suicidal ideation (controversial) Cardiovascular adverse effects, sudden death in patients with preexisting cardiac structural abnormalities (congenital abnormalities)

		Newer sustained release tablets: 18 mg, 27 mg, 36 mg, 54 mg (Concerta)		
Amphetamine compounds: Increases Norepinephrine (NE) and dopamine action by blocking reuptake,	Adderall, Adderall XR/ amphetamine (D, L)	Narcolepsy: 5–60 mg/day in divided doses ADHD: 5–40 mg/day (divided dose for immediate release and am only dosing for extended release)	ADHD in children from 6–17 ADHD in adults (Adderall XR) Narcolepsy (Adderall) Treatment resistant depression	Insomnia, headache, exacerbation of tics, nervousness, irritability, tremor, overstimulation, dizziness, anorexia, nausea, dry mouth, constipation, diarrhea, weight loss, can temporarily slow normal growth in children (controversial), sexual dysfunction long-term (impotence, libido changes) but can also improve sexual dysfunction short-term
Enhance NE and dopamine action in the dorsolateral prefrontal cortex, to improve attention, concentration, executive function and wakefulness	Other compounds: Vyvanse capsules: 30 mg, 50 mg, 70 mg	Immediate release tablets double scored: 5 mg, 7.5 mg, 10 mg, 12.5 mg, 15 mg, 20 mg, 30 mg	ADHD in children from 3–16 Narcolepsy Treatment resistant depression	
Enhance dopamine actions in basal ganglia to improve hyperactivity	Dexedrine, Dexedrine spansules, Dextro stat/ amphetamine (D)	Extended release tablet: 5 mg, 10 mg, 15 mg, 20 mg, 25 mg, 30 mg		<i>Life threatening side effects:</i> Psychotic episodes, especially with parental abuse Seizures, palpitations, tachycardia, hypertension, Rare activation of hypomania, mania or suicidal ideation (controversial) Cardiovascular adverse effects, sudden death in patients with preexisting cardiac structural abnormalities (congenital abnormalities)
Enhance dopamine and NE in medial prefrontal cortex and hypothalamus which likely improves depression, fatigue and sleepiness		Narcolepsy: 5–60 mg/day in divided doses, once daily in am for spansules ADHD: 5–40 mg/day divided doses for tablet, once daily in am for spansules		
Boosts Norepinephrine/ noradrenaline and possibly dopamine in prefrontal cortex	Strattera/ atomoxetine	0.5–1.2 mg/kg/day in children up to 70 kg 40–100 mg in adults	ADHD in adults and children over 6 Treatment resistant depression	Sedation, fatigue, decreased appetite, increased heart rate (6–9 beats/minute), increased blood pressure (2–4 mmHg),

(continued)

MECHANISM OF ACTION	BRAND NAME/GENERIC NAME	DOSE RANGE AND DOSE FORMS	INDICATIONS	SIDE EFFECTS
Blocks NE reuptake pumps Increases noradrenergic neurotransmission		Tip: Efficacy more likely at 1.4–1.8 mg/kg/day Capsule: 10 mg, 18 mg, 25 mg, 40 mg, 60 mg, 80 mg, 100 mg		insomnia, dizziness, anxiety, agitation, irritability, aggression, dry mouth, constipation, nausea, vomiting, abdominal pain, dyspepsia, urinary hesitancy, urinary retention (older men), sweating, dysmenorrhea, sexual dysfunction (men: decreased libido, erectile disturbance, impotence, ejaculatory dysfunction, abnormal orgasm; women: decreased libido, abnormal orgasm) <i>Life threatening side effects:</i> Increased heart rate and hypertension Orthostatic hypotension Severe liver damage (rare) Hypomania and possible mania induction, rare suicidal ideation and behaviors
Alpha 2 agonist Hypertension: stimulate alpha 2 adrenergic receptors in the brain stem: reduces sympathetic flow from CNS decreases peripheral and renal vascular resistance, heart rate and blood pressure	Catapres/clonidine Other Alpha 2 agonist used for ADHD: Tenex/guanfacine	0.2–0.6 mg/day in divided doses In children: 0.05–0.3 mg/day Scored Tablet: 0.1 mg, 0.2 mg, 0.3 mg Topical: 7day patch 0.1 mg/24 hours, 0.2mg/24 hours, 0.3 mg/24 hours	Hypertension ADHD Tourette's syndrome, substance withdrawal (opiates and alcohol), Anxiety disorders (PTSD and social anxiety disorder, Clozapine induced hypersalivation Menopausal flashbacks	Dry mouth, dizziness, constipation, sedation, weakness, fatigue, impotence, loss of libido, insomnia, headache, Major depression Dermatologic reactions especially with patch, hypotension, occasional syncope, tachycardia, nervousness, agitation, nausea, vomiting.

Interacts at imidazoline receptors		Injection 100 mg/ml, 500 mg/ml	Severe pain in cancer patients in combination with opiates.	<i>Life threatening side effects:</i> Sinus bradycardia, atrioventricular block, during withdrawal, hypertensive encephalopathy, cerebrovascular accidents and death (rare)
Central actions on alpha 2 receptors in the CNS causing behavioral changes (exact mechanism unknown and speculative)				
See Table 23.1 for details	Wellbutrin SR Wellbutrin XL	50–300 mg in divided doses (SR) 150–300 mg (XL)		ADHD
<hr/> Data for this table collected from <i>Essential Psychopharmacology: The Prescriber's Guide Revised and Updated Edition</i> , by Stephen Stahl, 2006, New York: Cambridge University Press. (Original edition, 2005)				

The alpha agonists have been used alone and as adjunct therapy to stimulant medications to help ADHD children and adolescents with hyperactivity, impulsivity, and aggression (Hunt, Arnsten, & Asbell, 1995; Hunt Minderaa, & Cohen, 1985). Because of the common symptom of insomnia in some ADHD children and adolescents, clonidine is also utilized for sleep.

Again, the pure-ADHD patient is very simple to treat, and once an effective medication and dosage are found, minimal changes are needed, other than when the stimulant dosage has to be increased as the child experiences growth spurts. The majority of pure-ADHD children are treated by their pediatricians, although there may be a few seen in psychiatric practices. The majority of the patients with ADHD in psychiatric practices are either adults with pure ADHD or children and adolescents with comorbidities (Sankaranarayanan et al., 2006). In the latter case the treatment can become very complex and difficult, and combinations of a variety of medications discussed in this chapter become medically necessary to treat, as per the additional diagnosis.

PSYCHOPHARMACOLOGICAL APPROACHES TO DEMENTIA

The prevalence rates of dementia disorders vary according to different diagnostic systems. Prevalence is estimated to be 1.2% based on criteria from the *ICD-9*, 3.1% based on the *ICD-10*'s criteria, 6.3% based on the *DSM-III-R*'s criteria, 9.6% based on the *DSM-IV-TR*'s criteria, and 7.4% based on "historical" criteria (Wancata, Borjesson-Hanson, Ostling, Sjogren, & Skoog, 2007).

According to criteria for dementia disorders delineated by the *DSM-IV-TR*, dementia is a cognitive disorder that involves multiple cognitive deficits that do not occur exclusively during the course of delirium (American Psychiatric Association, 2000). In this category of disorders, memory impairment and at least one of the following occur, representing a decline from a previous level of functioning and impairment in role function: aphasia, apraxia, agnosia, or disturbed executive functioning. There are three major categories of dementia disorders: cortical, subcortical, and mixed-features dementia.

Cortical dementias are classified as dementia of the Alzheimer's type, Alzheimer's disease, dementia due to Creutzfeldt-Jakob disease, and frontotemporal dementia (e.g., Pick's disease). Clinically, features seen are prominent memory impairment, aphasia, agnosia, and

apraxia. Dementia of the Alzheimer's type is the most common form of dementia. Dementia of the Alzheimer's type is a clinical diagnosis with insidious onset and gradual steady progression of cognitive deficits. The diagnosis of Alzheimer's disease is only rendered after medical evaluation does not reveal other causes for the dementia symptoms. This can be validated by microscopic examination of neural tissue. There are many forms of frontotemporal dementia, including Pick's disease, progressive subcortical gliosis, and amyotrophic lateral sclerosis. This subcategory of dementia has an earlier age of onset, with evidence of executive dysfunction, attention deficits, and personality changes with relatively spared memory and visuospatial functions. There are two types of Creutzfeldt-Jakob disease: (1) classic Creutzfeldt-Jakob disease, with early neurological signs and significant neuropsychiatric syndromes, is typically found in older individuals, and (2) variant Creutzfeldt-Jakob disease has delayed neurological signs with a longer clinical course and is found more commonly in younger adults. In both types of Creutzfeldt-Jakob disease, the prognosis is fatal.

Subcortical dementias are structurally and clinically distinct from cortical dementias. Individuals with subcortical dementias have less amnesia, agnosia, aphasia, and apraxia and more emotional incontinence, cognitive slowing, executive dysfunction, personality change, and attentional dysfunction. Etiologies of subcortical dementias include HIV, Huntington's disease, Parkinson's disease, and multiple sclerosis. HIV dementia evolves clinically with early decreased psychomotor and information-processing speed, verbal memory, learning efficiency, and fine motor function and later cortical symptoms of decreased executive function, aphasia, apraxia, and agnosia (reports of up to 30% in HIV populations). In the course of Huntington's disease, the triad of motor, cognitive, and psychiatric symptoms occurs. Up to 60% of Parkinson's disease patients have dementia. This form of dementia has subcortical (bradyphrenia, apathy, poor retrieval memory, decreased verbal fluency, and attention deficits) and cortical elements (executive dysfunction, visuospatial impairment, agnosia, anomia, aphasia, and apraxia) as these individuals develop cortical Lewy bodies. When dementia is due to multiple sclerosis, there are deficits in attention, memory, information-processing speed, learning, and executive functions.

There are dementia disorders that have both cortical and subcortical characteristics: vascular dementia, Lewy body variant of Alzheimer's dementia, and Lewy body dementia. Approximately 10% of the dementia disorders are reversible, including (1) structural central

nervous system abnormalities (vascular dementia, head trauma, subdural hematoma, normal-pressure hydrocephalus, multiple sclerosis), (2) psychiatric disorders with cognitive impairment that improves with treatment (major depression, substance dependence), (3) systematic and/or metabolic factors (hypothyroidism, hypercalcemia, hypoglycemia, thiamine, niacin, B12 deficiency, renal failure, hepatic failure, medications), and (4) infectious diseases (HIV, central nervous system infection).

The assessment of cognitive deficits and associated sequelae is an intricate process (American Psychiatric Association, 2007a). Dissimilar to evaluation strategies employed with other neuropsychiatric conditions, these assessments are usually more extensive and span multiple disciplines. Clinical history and mental status examinations, physical examinations, neuroimaging, laboratory data, neuropsychiatric testing, and collateral information from family members, caretakers, and primary care providers are all integral parts of this process. Clinicians must be attuned to elucidating the etiology and staging of dementia disorders. In addition to staging, the clinician must assess for comorbidities that are frequently associated with dementia, which include mood, sleep, and psychotic disorders. Differential diagnostic challenges include differentiation between delirium, amnesic disorders, mental retardation, mood disorders, substance use disorders, and psychotic disorders.

The psychiatric management of patients with dementia requires a multidisciplinary approach that is tailored to the stage of the dementia and neuropsychiatric presentation (American Psychiatric Association, 2007a). Psychosocial interventions are essential in the stabilization and treatment of these patients. Partnering with the family and/or caretakers, providing psychoeducation, and discussing safety issues such as provisions for falls, wandering, and driving, are ongoing in the treatment process. Other nonpharmacologic interventions are addressed in another section. Psychopharmacologic treatment in the geriatric population is very complex and requires knowledge of (1) the impact of aging on the absorption, distribution, metabolism, and elimination of certain medications; (2) potential sensitivity to side effects in the elderly (anticholinergic effects, orthostatic hypotension, sedation, parkinsonism, and extrapyramidal side effects); and (3) the treatment of concomitant medical illnesses and drug-drug interactions. There are very specific areas where the utilization of pharmacotherapy in patients with dementia disorders has proved effective. Effective pharmacologic treatments for cognitive symptoms, psychosis, agitation, delirium, depres-

sion, and sleep disturbances have been reported in the literature.

Cholinesterase inhibitors such as tetrahydroaminoacridine (tacrine), donepezil (Aricept), galantamine (Reminyl, Razadyne), and rivastigmine (Exelon) are all efficacious in improving cognition and psychotic symptoms associated with dementia of the Alzheimer's type and dementia of Parkinson's disease (Schatzberg et al., 2007). Although cholinesterase inhibitors are the mainstay in the treatment of cognitive symptoms, other agents have also been used. Memantine is a noncompetitive NMDA antagonist, and selegiline is a monoamine oxidase inhibitor; these agents are second line in the armamentarium for dementia disorders (Schatzberg et al., 2007). Antioxidants (alpha-tocopherol) have been shown to be protective in slowing decline in patients with moderate Alzheimer's dementia (Bourgeois et al., 2007) and ergoloid mesylates may be beneficial to vascular dementia patients (Kennard, 2006).

To manage psychosis and agitation, clinicians must ascertain if the agitation is originating from physical discomfort, depression, delirium, or sleep deprivation. Once it has been established that there is no underlying physical or psychiatric illness precipitating the agitation or psychotic symptoms, there are pharmacologic and nonpharmacologic options to consider. From the pharmacologic perspective, a clinician can optimize cholinesterase inhibitors and/or the judicious use of antipsychotic, anxiolytic, anticonvulsant, antihypertensive, hypnotic, and melatonin therapies for target symptoms. Many of these medications are used even though they do not have approval from the FDA, and all of the antipsychotic agents carry a black box warning for cerebrovascular accidents in elderly patients (Leigh-Pemberton et al., 2006; see Table 23.3a and Table 23.3b). In instances where medication management of psychosis and/or depression is not possible given medical circumstance, electroconvulsive therapy is a viable option. The medical and behavioral fragility of patients with dementia warrants close collaboration between medical personnel, psychiatrists, and other mental health providers to ensure safe and effective stabilization and treatment.

PSYCHOPHARMACOLOGICAL APPROACHES TO PERSONALITY DISORDERS

Personality disorders have been described as an "enduring subjective experience and behavior that deviates

from cultural standards, [that] are rigidly pervasive, have an onset in adolescence or early adulthood, are stable through time, and lead to unhappiness and impairment” (Sadock & Sadock, 2003, p. 800). Ten distinct disorders have been identified (see Table 23.10), and they are stratified into three clusters (Clusters A, B, and C) based on shared features (Zanni, 2007). Classifications in future editions of the *DSM* may not utilize these same delineation patterns because these clusters have not been consistently validated from a research perspective (American Psychiatric Association, 2000).

Two recent studies report the overall prevalence of personality disorders to be 9.1% (Lenzenweger, Lane, Loranger, & Kessler, 2007) and 14.79% (Grant, Hasin, Stinson, Dawson, Chou, Ruan, & Pickering, 2004). Cluster C (avoidant, dependent, and obsessive-compulsive disorders) is reported to have a prevalence rate of 6%, while cluster B (antisocial, borderline, histrionic, and narcissistic personality disorders) has a prevalence rate of 1.5%, and cluster A (paranoid,

schizoid, and schizotypal personality disorders) 5.7% (Lenzenweger et al., 2007). At 7.88%, obsessive-compulsive personality disorder has the highest prevalence rate of any personality disorder, according to Grant et al.’s study (2004). Borderline personality disorder has a significant amount of associated disability and impaired function. The prevalence rate of this personality disorder is 5.9% and is equal in males and females (Grant et al., 2008).

Previously, etiologies of personality disorders were thought to be explained solely by psychological theories. Currently, a theory that involves a more complex interaction between genetic and environmental factors and their contributions to the regulation of perception, cognition, affect, and impulse exists (Howland, 2007; Soloff, 2000). In support of this theory, neuroimaging studies of patients with borderline personality disorder have shown the presence of structural and functional variations when compared to the general population. (Oldham, 2005,). With the increasing knowledge base

23.10

Diagnostic Categories with Common Pharmacotherapy Treatment Strategies

CLUSTER A	CLUSTER B	CLUSTER C
Paranoid personality disorder Valium Haldol Orap	Antisocial personality disorder Psychostimulants Tegretol or Depakote if EEG abnormal B-adrenergic antagonist for aggression	Avoidant personality disorder B-adrenergic antagonist SSRI antidepressants
Schizoid personality disorder Antidepressant Antipsychotic Psychostimulants	Borderline personality disorder Antipsychotics SSRI Antidepressant Benzodiazepines Anticonvulsant mood stabilizers	Dependent personality disorder Imipramine SSRI antidepressants Benzodiazepines
Schizotypal personality disorder Antipsychotic Antidepressant when indicated by depression	Histrionic personality disorder Lithium Narcissistic personality disorder Antidepressants	OC personality disorder Klonopin Benzodiazepine with an anticonvulsant mood stabilizer Clomipramine Prozac

From *Synopsis of Psychiatry: Behavioral Sciences/Clinical Psychiatry* (9th ed.), by B. J. Sadock & V. A. Sadock, 2003. Philadelphia: Lippincott Williams and Wilkins.

of the neurotransmitters' possible roles in the dimensions of personality disorders, psychopharmacologic research and treatment have increased (Soloff, 2000).

Diagnosing a personality disorder requires careful history gathering, collateral information whenever possible, and following an individual longitudinally in the clinical setting. These disorders require demonstration of long-term patterns of maladaptive functioning in various domains. Developmental considerations are also important during the assessment phase. According to the *DSM*, traits of a personality disorder may appear in childhood but not persist into adulthood. Moreover, there are developmental parameters regarding the diagnosis of personality disorders. For example, symptoms suggestive of a personality disorder that occur prior to adulthood must exist for at least 12 months, with the exception of antisocial personality disorder. Antisocial personality disorder cannot be diagnosed in individuals under the age of 18 (American Psychiatric Association, 2000). In addition to developmental factors, a person's ethnic and cultural factors must also be considered during diagnosis. Within the context of assessment, cultural practices and challenges associated with acculturation require clinicians to seek expertise, if needed, from professionals who are knowledgeable about the individual's social, cultural, and religious background.

To assist with diagnosis, psychometric instruments can be helpful. The Minnesota Multiphasic Minnesota Personality Inventory (Butcher, Altis, & Hahn, 2004) and the SCID-II (First, Spitzer, Gibbon, & Williams, 1997) are examples of diagnostic instruments that can assist with an evaluation for a personality disorder.

Treatment and management strategies for patients with personality disorders necessitate a multidisciplinary approach that is tailored to the specific disorder. Evidence-based treatment consists of various types of psychotherapies and the use of pharmacotherapy as an adjunctive option. The majority of the pharmacotherapy trials have been focused on the treatment of borderline personality disorder (Soloff, 2000). Impulsive aggression and affective instability are core symptoms of borderline personality disorder that have proved responsive to pharmacotherapy (Hollander, Swann, Coccaro, Jiang, & Smith, 2005; Koenigsberg et al., 2001). Other personality disorders in which aggression and impulsivity are prominent, such as the remaining Cluster B personality disorders, have also demonstrated improvement with pharmacotherapy agents that have mood-stabilizing properties (see Table 23.2). In addition, individuals with schizotypal personality disorder have clinically improved with typical and atypical an-

tipsychotic medication (Koenigsberg Reynolds, & Goodman, 2003; Schatzberg et al., 2007).

PSYCHOPHARMACOLOGICAL APPROACHES TO SUBSTANCE ABUSE DISORDERS

Substance-related disorders are a constellation of disturbances associated with toxic exposure, medication side effects, and the ingestion of a drug of abuse (American Psychiatric Association, 2000). The lifetime prevalence for substance use disorder is 14.6%, with the age of onset at 20 years of age (Kessler et al., 2005). The *DSM-IV-TR* stratifies these disorders into two categories: (1) substance use disorders (substance dependence and substance abuse) and (2) substance-induced disorders (substance intoxication, substance withdrawal, substance-induced delirium, substance-induced persisting dementia, substance-induced persisting amnesic disorder, substance-induced psychotic disorder, substance-induced mood disorder, substance-induced anxiety disorder, substance-induced sexual dysfunction, and substance-induced sleep disorder). Substance-related disorders are often comorbid with other psychiatric disturbances. Here we will address the pharmacologic treatment of abuse of the following substances: nicotine, alcohol, sedatives, opioids, amphetamines, and cocaine.

In addition to a comprehensive medical evaluation, clinicians are charged with gathering historical information from the patient and, if consent is obtained, collateral sources. During the psychiatric evaluation, the psychiatrist has a duty to explore for potential comorbid psychiatric disturbances and inquire about current and previous mental health and substance disorder treatments. The individual's current and previous substance use and the effects on psychosocial, behavioral, cognitive, and physiological functioning are essential domains to assess (American Psychiatric Association, 2006).

During the psychiatric evaluation, the psychiatrist screens for the 11 classes of substances listed in the *DSM-IV-TR*: nicotine, alcohol, sedatives (hypnotics or anxiolytics), opioids, amphetamines (sympathomimetics), cocaine, cannabis, hallucinogens, inhalants, phenylcyclidine, and caffeine. From a diagnostic standpoint, the distinction between dependence and abuse involves two specific criteria: tolerance and withdrawal, which are present in dependence but not in abuse. In both disorders, individuals demonstrate a maladaptive pattern of substance use over a 12-month period that has

led to impairment in daily functioning. Hallucinogens, inhalants, and cannabis result in only minor physical dependence; therefore users of these substances do not experience withdrawal symptoms (Schatzberg et al., 2007). However, they still experience considerable functional impairment. Other drugs, such as nicotine, have less functional impairment but lead to significant physical dependence.

The FDA has approved several pharmacologic treatment options for nicotine dependence. First-line drug therapies consist of: (1) the nicotine replacement therapies, (2) bupropion, and (3) varenicline (America Psychiatric Association, 2006; Connery & Kleber, 2007). The five smoking cessation agents classified as nicotine replacement therapies provide nicotine in gum, patch, spray, lozenger, and inhaler forms. Varenicline is the latest FDA-approved medication for cessation of smoking. Varenicline has selective partial agonist activity at the neuronal nicotinic acetylcholine receptor; it prevents dopaminergic activation produced by smoking and diminishes nicotine craving and withdrawal symptoms (Coe et al., 2005; Connery & Kleber, 2007; Rollema et al., 2007). Second-line medications used to promote smoking cessation are clonidine, which decreases sympathetic activity in the locus coeruleus of the brain abating withdrawal symptoms (Sadock & Sadock, 2003). Nortriptyline also appears to be effective for smoking cessation, but the mechanism of action is not clear (Sadock & Sadock, 2003).

The psychiatric management of alcohol dependence begins with monitoring for alcohol withdrawal. Symptoms of alcohol withdrawal can occur 4–12 hours after alcohol intake is either reduced or ceased. The withdrawal phase is usually resolved after 4–5 days. During this time frame, an individual who is alcohol dependent may develop delirium, seizures, psychotic symptoms, and hemodynamic instability. This portion of the treatment phase necessitates careful medical observation and treatment in conjunction with psychiatric management. Hydration is provided to prevent dehydration, which is exacerbated by diaphoresis and fever associated with withdrawal delirium (Sadock & Sadock, 2003). Thiamine is given as well to prevent the development of Wernicke-Korsakoff syndrome, which results from thiamine deficiency from malnutrition or malabsorption (Sadock & Sadock, 2003). To improve the homeostasis of the individual's central nervous system, numerous treatment options can be utilized during the withdrawal period. These include benzodiazepines, anticonvulsants, and clonidine. Diazepam and chlordiazepoxide, longer-acting benzodiazepines, are more commonly used for alcohol detoxification.

Lorazepam and oxazepam, the intermediate benzodiazepines, are less of a risk for accumulation and overdose in patients who suffer from hepatic complications (Bourgeois et al., 2007). Antipsychotics are used to treat agitation and impaired reality testing in this patient population. After the alcohol withdrawal phase, clinicians can use specific medications in the maintenance phase of alcohol dependence treatment. For example, disulfiram, naltrexone (oral and intramuscular formulations), and acamprosate are FDA approved and are evidence-based treatment options that help prevent alcohol relapse. Ondansetron is used clinically too but is not FDA approved (Mann, 2004).

Similar to alcohol, other sedatives and hypnotics also carry the risk of physical and psychological dependence. These medications are all cross-tolerant and have the same pharmacological effect. They include barbiturates, benzodiazepines, and glutethimide and methaqualone (Schatzberg et al., 2007). The onset of the withdrawal phase varies based upon the half-lives of the agents and can range from 12–16 hours up to 5 days. Grand mal seizures can occur 1–3 days after use of a shorter-acting agent and up to 5–10 days after use of a longer-acting agent. Approximately 50% of patients who have grand mal seizures are at risk of developing delirium with psychotic symptoms. Once the clinical course has advanced to delirium, withdrawal from the substance can result in death. This is particularly true when the sedative in question is a barbiturate. The pharmacological management for benzodiazepine intoxication reversal is the FDA-approved flumazenil. Withdrawal from sedatives is managed pharmacologically by the use of longer-acting sedatives (e.g., diazepam, chlordiazepoxide, phenobarbital), which are gradually tapered as the signs and symptoms of withdrawal resolve (Bourgeois et al., 2007). Strategies for the maintenance treatment of individuals who have traversed through the withdrawal phase are not well delineated. The strategy of substituting clonazepam for shorter-acting agents has been debated in the literature due to clonazepam's risk of dependence (Galpern, Lumpkin, Greenblatt, & Shader, 1991; Schatzberg et al., 2007). Pregabalin is a neuromodulator that has shown favorable preliminary results in the successful treatment of benzodiazepine dependence (Oulis et al., 2008).

The class of opiates is inclusive of legally prescribed medications and illicit drugs. Withdrawal symptoms can begin as early as 6 hours after cessation of heroin or other shorter-acting opiates. Sympathetic nervous system responses can occur approximately 24 hours after abstinence and resolve within 10 days. With

the exception of opiate overdose, the untreated opiate withdrawal phase does not carry the same medical risk as alcohol withdrawal. In the case of opiate overdose, respiratory function must be supported and naloxone should be given to reverse opioid intoxication. Methadone, clonidine, buprenorphine (mixed opiate agonist-antagonist), naltrexone, and naloxone are used for the psychiatric management of opiate withdrawal (Kosten, Kleber, & Morgan, 1989; Schatzberg et al., 2007; Umbrecht, Montoya, Hoover, Demuth, Chiang, & Preston, 1999). Once the opiate withdrawal phase has passed, maintenance therapeutic options can be introduced to reduce the likelihood of relapse. Methadone daily maintenance has been the mainstay for opiate dependence for decades. LAAM (levo-alpha-acetylmethadol) is a longer-acting compound than methadone and is taken 3 times weekly. Naltrexone and naloxone are both opiate antagonists. They can both be given to block opiate receptors, which eliminates the euphoric effects of opiates. Naltrexone is the better option of the two for clinical use. Naloxone is not as potent orally and is shorter acting. A combination formulation of buprenorphine and naloxone (Suboxone) has also been approved by the FDA and used for maintenance treatment of opiate addiction.

Amphetamine and cocaine have similar properties and are classified as stimulants. In cocaine and amphetamine intoxication, individuals may experience autonomic hyperarousal with hypertension, tachycardia, agitation, seizures, and perceptual disturbances. The intoxication phase may require treatment of medical and psychiatric symptoms. Stimulant withdrawal symptoms are generally self-limited. Depressive symptoms may appear or increase during the withdrawal phase, which may last anywhere from weeks to months. This condition requires psychiatric monitoring. Many pharmacologic agents have been utilized during this phase without proved efficacy. At present, there are no FDA-approved pharmacotherapy options for the treatment of either cocaine or amphetamine dependence. Regarding maintenance treatment of cocaine dependence, the agents being utilized include disulfiram, topiramate, and modafinil (American Psychiatric Association, 2006). In individuals who were being treated for opiate dependence with methadone, bupropion with contingency management improved clinical outcomes in the treatment of cocaine dependence (Poling et al., 2006). Tiagabine and baclofen both demonstrated therapeutic efficacy over placebo in the treatment of cocaine dependence (Gonzalez et al., 2007; Shoptaw, Yang, Rotheram-Fuller, Hsieh, Kintaudi, Charuvastra, & Ling, 2003). A limited number of studies have shown the efficacy of

disulfiram for cocaine dependence, and other medications (e.g., ecopipam and citicoline) are being investigated (O'Leary & Weiss, 2000; Petrakis, Carroll, Nich, Gordon, McCance, Frankforter, & Rounsaville, 2000; Schatzberg et al., 2007).

In summary, we are still in the early stages of developing pharmacological treatments for substance abuse and have made more inroads in the treatment of the acute withdrawal phase than in the maintenance phase.

SPECIAL ISSUES

In addition to the information in this chapter regarding medications and their indications, dosing, and side effects, there are other areas of concern that must be addressed before and during pharmacological treatment.

Geriatric Psychopharmacology

Treatment of geriatric patients can prove to be tedious and difficult. Before medications are chosen, it is important to complete a medical/psychiatric evaluation. A list of medical conditions and medications can be very useful and help to avoid untoward drug-drug interactions. Elderly patients experience changes in their level of absorption, distribution, enzyme production, and medication elimination (Kompolti & Goetz, 1998). These physiological changes require smaller doses to acquire the desired treatment goal than those given to the general adult population. Side effects must also be monitored closely because of polypharmacy due to associated medical conditions. Some side effects that are minor in adults may be major in the elderly because of their difficulty tolerating mental status changes and electrolyte imbalances.

Child and Adolescent Psychopharmacology

Psychopharmacology with children and adolescents is equally complicated. Once the assessment is complete and target symptoms have been identified, a medication is chosen. Education regarding expectations, targeted symptoms, duration of treatment, and potential side effects is essential before parents consent to medications. Most children have a faster drug metabolism than adults because they have greater hepatic capacity, more glomerular filtration, and less fatty tissue (Sadock & Sadock, 2003). This means that medications and their metabolites are eliminated faster. This rapid metabolism may shorten the half-life of medications in children. As a

result, we typically start low and slowly increase. Daily dosing may need to be divided into 2–3 doses per day to maintain therapeutic blood levels.

Cultural Psychopharmacology

Studies have consistently shown that different ethnic populations respond differently to psychopharmacological interventions; this is referred to as ethnopsychopharmacology. This becomes an issue for members of certain races, who may be characterized as either ultrarapid metabolizers or very slow metabolizers (Lim, 2006).

Medical Conditions and Psychopharmacology

Another important issue is the patient's medical condition. Hepatic and renal insufficiency can greatly impair the patient's ability to breakdown and eliminate metabolites, thus placing the patient at high risk of toxicity. Thus in addition to familiarizing oneself with the desired affects of medications, it is very important to educate patients about the adverse and toxic effects of medications, especially medically challenged patients. A more sensitive area of treatment with medication is pregnancy and breast-feeding. The goal is usually to remove all psychotropic medications; however, there are times when the benefits outweigh the risks and some form of medication is indicated.

CONCLUSION

Psychopharmacology is taught during medical school; however, this is a subject that is never mastered and requires constant reading, continuing education, ongoing research, and collaboration with peers so the clinician can remain abreast of new discoveries and updates. We often refer to the field as “the art of medicine,” which is a good description of the tedious process of trying to find the exact medication, exact dose, and exact combination needed for each patient based on his or her specific condition, metabolism, genetics, and potential to adhere to recommendations. Because psychotropic medications are considered mind-altering medications and some of our patients present with poor judgment and insight, it is essential that we help patients be informed so that they can autonomously make a choice about proceeding with treatment options, which may include psychopharmacology.

Integrative Clinical Hypnosis

Jeanne Taylor Hernandez

Hypnosis is a term derived from the Greek word meaning “sleep.” Long before it was used in medicine, it was practiced by the Druids, the Celts, and the Egyptians, who built temples specifically for relaxation and healing. The American Psychological Association defines hypnosis as “a social interaction in which one person, designated the subject, responds to suggestions offered by another person, designated the hypnotist, for experiences involving alterations in perception, memory and voluntary action” (Kihlstrom, 1985, p. 385). Hopefully, this is for the sake of some change the patient desires. Hypnosis is also a formalized pathway into a trance or dissociation, and hypnotherapy involves a programmed trance for therapeutic purposes. It can bypass or lower the critical thinking filters of the cognitive mind in order to access unconscious processes, possibly those involving alterations in perception, memory and voluntary action, and creating a condition of heightened suggestibility. Trance occurs naturally to most of us when we become fully absorbed in a task to the exclusion of whatever else is occurring, when we focus intently on just one aspect of an experience, and when we dissociate from an experience to the point of losing track of whatever else we are doing, for example, forgetting to monitor what we are snacking on when we watch television, or losing track of time during an activity.

The conscious mind includes cognitive processing, awareness, concentration, and critical thinking skills. The unconscious mind is always working, storing and holding information in short- and long-term memory.

With the conscious and unconscious minds working together, you can be aware of many things at once. Considerable movement is generated by the unconscious mind without much thought—your heart beats, you breathe, you have a strong set of survival skills, you scratch an itch, you have knee-jerk reactions and habits. Wearing your heart on your sleeve indicates what is going on in your unconscious mind and is not being shielded by your conscious mind. Deeper processes in the unconscious mind define who you uniquely are—your spiritual self, your personality, or your soul. We might say that your conscious mind consists of awareness, cognitive skills, and recall of memories, and your unconscious mind is in charge of everything else, including basic physiological functioning. As permanent as your spiritual or core self might be, your unconscious mind is infinitely adaptive, potentially with both positive and negative outcomes, whereas your conscious mind may have to wade through reasoning processes and habits to make changes. Therein lies the potential value of hypnotherapy.

Formal hypnosis depends upon dissociation (disassociation) from normal thought processes and awareness, and a relative shift to the unconscious mind. During that dissociation, the patient may distort time, accentuate only one part of an experience, or see a situation in a completely different light. Such dissociation may occur during either trauma or trance.

During therapeutic trance, the patient may shut off pain or influence healing, immune functions, heart rate,

blood flow, and autoimmune responses not commonly accessed in normal consciousness. Actually, the hypnotist or hypnotherapist is merely guiding the patient to self-hypnosis. Unless the state is induced with psychoactive substances, the patient is the one who suspends vigilance, and his or her ability to do so is likely to depend upon the relationship that he or she has with the hypnotist; the skill of the hypnotist inducing the trance; the safety of the situation and environment; the patient's level of hypnotizability, expectancy that he or she will receive benefit and relief, and his or her desire or need for the trance (pain itself could put the patient into a trance state); and the patient's past experience with trances, ranging from dissociative disorders to meditation to past hypnosis training.

HISTORY OF HYPNOSIS

The first use of hypnosis in modern times was medical. Physician Franz Mesmer (1734–1815) was interested in the effect of physical energy and magnetism on the body and spirit. He placed his patients in a tub of iron filings and, with wide sweeps of his arm, made “passes” up and down the patients' bodies. The success of the practice, termed mesmerism, was attributed to animal magnetism; however, the benefits were probably due to the hypnotic effect of his arm-waving ritual. Practical uses of mesmerism were discussed in the 1800s by Oliver Lodge in the United States and by the French Academy of Medicine. James Braid (1795–1860) in Scotland coined the word “hypnosis” in 1843, thinking that it might be a stage of sleep that influenced the nervous system, and distinguishing it from the state of mental concentration. Braid concluded that the use of hypnotic suggestion itself diverted patients away from critical thinking and led them into trance. Ivan Pavlov, in the early 1900s, viewed hypnosis as an incomplete sleep state that allowed patients to mentally separate themselves from their surroundings.

Surgeon John Esdaile (1808–1859) began using trance inductions while doing surgery in India when there were no other anesthetics available; he found his hypnotized patients to have increased resistance to infection, greater comfort, and quicker recovery times. The School of Hypnotic Study in Nancy, France, theorized that trances were normal phenomena. Neurologist Jean-Martin Charcot (1825–1893) saw hypnosis not only as a treatment for hysteria, which was a common diagnosis at the time, but also as part of the hysteria process. Current brain research shows all the above to be valid. Psychiatrist Pierre Janet (1849–1947) intro-

duced the notion of dissociation as a split from cognitive consciousness, which he saw as sometimes normal and sometimes related to emotional disorders. Psychiatrist Sigmund Freud (1856–1939) heightened attention to hypnosis through his use of it to access the unconscious mind and its memories.

There was a long period of disinterest in hypnosis from the mid-1840s to the 1950s, in part because Freud stopped using it as a therapeutic vehicle, but even more so due to the introduction of chloroform and ether, which were quicker, easier, and more predictable anesthetics for surgery. In the 1950s, psychologist Clark Hull (1933/2002) reviewed its uses, one of which was as a means to explore the inner workings of the mind. Psychiatrist Milton Erickson began studying the mechanisms of therapeutic trances as well as trances used in indigenous cultures. Erickson has been revered for his understanding of the unconscious mind and how to access it for pain relief and psychotherapeutic gain. The Society for Clinical and Experimental Hypnosis was founded in 1949, and the American Society of Clinical Hypnosis in 1957. Hypnosis was endorsed by both the American Psychological Association and the American Medical Association in the late 1950s. The British Medical Association in 1958 endorsed its use as an anesthetic in certain surgical situations.

Again, hypnosis is rarely therapy itself but is rather a vehicle for therapy or for facilitating change, particularly where the conscious mind would otherwise be in the way (see Table 24.1). The list of conditions where hypnosis should not be used in therapy is far shorter than that of conditions where it may be effectively used. In fact, there are few conditions for which self-hypnosis would not be useful, at least adjunctively; it is even used by athletes and performers in a split state of consciousness, when they are aware of their surroundings and working in trance with both mind and body. There are situations when the use of hypnosis alone is powerful, such as helping someone relax deeply, or diverting a person's focus from a situation (as in surgery). Speaking with hypnotic tones and phrasing can potentially soothe babies, pets, and those who speak a different language, if soothing is the goal.

CENTRAL MECHANISMS

Central Mechanisms of Hypnosis

Hypnosis has been theorized to be magical, energy related, sleep related (by Braid and Pavlov), psychoso-

24.1 | Common Applications of Hypnosis

Psychotherapy Uses

Ego strengthening	Smoking cessation
Self-confidence	Eating disorders
Anxiety	Writer's block
Depression	Performance enhancement
Problem solving	Performance anxiety
Accessing memories	Public speaking fear
Changing self-image	Social phobias
Marriage therapy	Fear of flying
Stress reduction	Muscle relaxation
Coping techniques	Assertiveness training
Sexual dysfunction	Positive thinking
Tics	Behavior change
	Habit change

Medical Uses

Dental procedures	Analgesia/anesthesia
Gagging	during procedures
Bruxism	Colonoscopies
Headaches	Blood drawing
Burns	Gynecological procedures
Hypertension	Allergies
Nausea and emesis	Palliative care
Skin rashes and warts	Chronic pain
Bone growth	Chronic disease
Preoperative preparation	management
Post-operative pain and recuperation	Immune and autoimmune disorders

matic, pathological (by Charcot), dissociative (Bowers, 1992; Hilgard, 1965; Janet, 1910), and the consequence of normal suggestibility (Bernheim, 1884/1963)—all of which are somewhat true. Some have thought that the hypnotic response was a function of the positive expectation of the magnets used by Mesmer and Erickson's positive orientation, which involved enhancement of the patient's self-esteem and competency; this is also somewhat true. Many recognized the role of the unconscious mind in psychosomatic symptom formation and began to see that some people were more easily hypnotized than others and that these same people more often developed psychosomatic symptoms. Recent studies indicate that there is in fact something of a link between the two (DuHamel, Difede, Foley, & Greenleaf, 2002; Roelofs, Hoogduin, & Keijsers, 2002; Younger, Rossetti, Borckardt, Smith, Tasso, & Nash, 2007).

How does all this happen? The introduction of PET scans, functional fMRIs, and measurement of event-related potentials in the brain, all of which highlight brain activity, have helped considerably to explain it. Rainville and Price's (2003) event-related potential studies show that hypnosis is indeed an alteration of the normal state of consciousness; specifically, there are changes in arousal and attentional systems. Bowers (1992, 1994) theorized that during hypnosis one dissociates from central control and that imagery is part of the process. Recent studies using PET scans show that hypnotic hallucinations are different from mental imagery and are consistent with scans of the brains of people who are actually seeing what is hallucinated (Kosslyn, Thompson, Costantini-Ferrando, Alpert, & Spiegel, 2000). The effect of suggestion in hypnotic induction is measurable in event-related potentials (Killeen & Nash, 2003). The wording of a suggestion is very important, and the suggestion alone can dissociate the patient from either what he or she was previously concentrating on or from what he or she would otherwise be monitoring; this is called suspended vigilance (D. Spiegel, 2003). Recent fMRI and PET scan research shows that during the hypnotic process there is a simultaneous increase in activity in some areas of the brain and selective shutting down of others. Research specifically shows dissociation from centralized activity and concurrent changes in the normal integrated physiological response patterns, resulting in a trance state (Lee et al., 2007). Hypnosis seems to involve more activity in the hippocampus (memory) and less activity in the amygdala (emotion; DeBenedictis & Sironi, 1988). This is why hypnosis can interrupt the attachment between (and decouple) emotional and cognitive information and sensory processing, thereby taking the physical sting out of an emotional event and taking the physiological sting out of an emotional one. Those who are highly hypnotizable are, while hypnotized, relatively better at actively not paying attention to what they actually know is in the field; this is partially a function of a shift from the dominant use of activation of one side of the brain to the other, engaging the patient's ability to feel or imagine things differently from how they were before (Gruzeliier, 2006). A PET scan study shows that the decreased vigilance in hypnotic relaxation is similar to that of slow-wave sleep, and that changes in the parietal lobe affect orientation, attention, and perception (Rainville, Hofbauer, Paus, Duncan, Bushnell, & Price, 1999). Specifically, hypnotic induction leads to changes in several areas of the brain, including areas of the anterior cingulate cortex, thalamus and brain stem, which indicates (1) the relevance of the suggestion itself, (2) altered sensation, and

(3) reinterpretation of perceptual experience. All this helps explain how hypnosis helps patients change old patterns and make psychotherapeutic advances.

High and Low Hypnotizability

Hypnotizability is a relatively stable trait that is independent of intelligence. Approximately 15% of people, called Highs, are highly susceptible to hypnosis; 65% are moderately susceptible; and 20%, called Lows, are not very susceptible (Hilgard, 1965). These percentages have held over time, such that we can agree that some of us are more hypnotizable than others. Other variables determining hypnotic success are the hypnotherapist's skill, the motivation level and expectancy of both parties, the patient-hypnotist relationship and rapport, the patient's need for trance, and other variables in the induction process, such as the environment. In regard to skill and rapport, the better the hypnotherapist can blend in with the patient's internal experience during their interaction, the more likely he is to lower the patient's vigilance and put the conscious mind to rest (see Bandler & Grinder, 1996; Gilligan, 1987; Haley, 1986, for extensive coverage of this principle).

Those in a hypnotic state can selectively ignore what is in their perceptual field while still knowing what is there, so that they can shift their focus from pain, unhappiness, or helplessness to something more acceptable or productive and make the best of it (Gruzelier, 2006). In general, Highs seem to have what Gruzelier (2006) calls "superior abilities in absorption, creativity, dissociation, attention and vividness of imagery" (p. 20). Highs' better absorption is related to a shift in brain activity from the right hemisphere's global orientation to the left hemisphere's more narrow local orientation (Gruzelier, 2006). Partly responsible for that is their relatively greater neurophysiological and cognitive flexibility in transferring processing from the right to left hemispheres, and vice versa (Evans, 1991; Horton, Crawford, Harrington, & Downs, 2004). fMRIs show that they have significantly larger corpus callosa than Lows, which allows for the transfer of problem-solving information between the two hemispheres.

Hypnotizability level also seems to influence the effectiveness of hypnosis for pain management. Specifically, Highs may be better at tuning in to the body, but also at inhibiting pain from their conscious awareness. The somatosensory brain activity that increases during pain is reduced under hypnotic analgesia because hypnosis can short-circuit or decouple the perceptual (sensory, affective, cognitive, and behavioral) aspects of pain and also the body's automatic immune or autoimmune

responses to it (DePascalis, Magurano, & Bellusci, 1999; Faymonville et al., 2003). In fact, fMRI studies show that both real and hypnotically hallucinated pain produce similar activity in similar parts of the brain, although perception of hallucinated pain was less than the actual induced pain (Raij, Numminen, Närvänen, Hiltunen, & Hari, 2005). Highs and Lows in pain respond differently to hypnotic analgesia. Studies have shown that as pain ratings increased and subjects were offered hypnotic analgesia, Highs had relatively less pain-related brain activity than Lows, including less sympathetic activity, with differences in laterality accounting for differences in pain perception (Croft, Williams, Haenschil, & Gruzelier, 2002; DePascalis, 1999).

Testing Hypnotizability

There are a number of scales and clinician-administered tests to measure hypnotizability, suggestibility, and absorption, which are all slightly different. There is, however, some concern that patients' previous experience with hypnosis, including the testing process, could contaminate research findings (Yapko, 1993); people do become more proficient at hypnosis with practice. Testing during a therapy session could also interfere with the therapeutic relationship. Accurate testing is, however, very important if the goal is to use hypnosis as the main anesthesia during surgery. In such cases, form C of the comprehensive hour-long Stanford Hypnotic Susceptibility Scale (Weitzenhoffer & Hilgard, 1962) would be appropriate. Weitzenhoffer (2002) recommends using the Stanford Profile Scales of Hypnotic Susceptibility I and II (Weitzenhoffer & Hilgard, 1963), and using a cutoff score of 10 with form C of the Stanford Hypnotic Susceptibility Scale, to be sure that the patient can achieve a hypnotic state.

The Stanford Hypnotic Clinical Scale (Morgan & Hilgard, 1978–1979), which has versions for adults and for children, takes 25 minutes. The Hypnotic Induction Profile (H. Spiegel & D. Spiegel, 1978) takes only 5–15 minutes; it uses an eye rolling technique that is an autonomic measure of hypnotizability. For use in research or other group settings, the Harvard Group Scale (Shor & Orne, 1962) can be administered via tape recording. The Hypnotic State Assessment Questionnaire (Kronenberg, LaClave, & Morrow, 2002) assesses patients' hypnotic state only at one point in time but can still be useful clinically or in a research setting.

Suggestibility and hypnotizability are slightly different, and Weitzenhoffer (2002) suggests that failure to differentiate the two may be the reason why some research studies fail to demonstrate successful use of

hypnosis. The Waterloo-Stanford Group Scale of Hypnotic Susceptibility (Bowers, 1993) is a group version of form C of the Stanford Hypnotic Susceptibility Scale (Weitzenhoffer, 2002) and may be a good measure of suggestibility.

There are still other ways to assess hypnotizability, particularly for the seasoned therapist or hypnotist. Kirsch (1997) suggests that success with the first induction administered is a good indicator of future performance. Kessler, Dane, and Galper (2002) feel that a conversational assessment of hypnotizability may give the seasoned hypnotherapist the information he or she needs, including information about the patient and cues about his or her language use, experiences, and preferences. To assess experience with trance, the therapist might also ask about previous hypnotic experiences; past trauma or abuse; response to anxiety; any dissociative tendencies in various realms of life; long-distance running; absorption when watching TV; characteristics that are hallmarks of attention deficit disorder; and right/left brain characteristics, which might include left-handedness, artistic interests, and musicality. Experiences with and interest in yoga or meditation, mind/body sensitivity, psychological mindedness, and a vivid imagination—including the possession of imaginary friends during childhood—all might be indicators of response to induction.

EFFICACY AND EFFECTIVENESS

Research on the effectiveness of hypnosis is increasing. One reason is that fMRIs and other brain research techniques are validating its potential power. Partly due to the high cost of medical treatment and partly due to heightened awareness of their importance, emphasis on interdisciplinary treatment approaches to mental and physical diseases and pain, such as hypnosis, has increased. The National Institutes of Health no longer even sees hypnosis as an alternative medical treatment; it is considered mainstream. Good research on hypnosis is important because without published results, hospitals and insurance companies will not support its use. Hypnosis is not included in best practice guidelines for some conditions simply because there is not enough research to show its benefits over other psychological or medical interventions. Hence, while medical hypnosis research has been moving forward, the hypnosis community has been working harder on developing definitions, guidelines for practice, and research on effectiveness (how well hypnosis works in the real world) and efficacy (how well it works in controlled situations;

Chaves & Dworkin, 1995; Gay, Philippot, & Luminet, 2002; Nash, 2004; Wild & Espie, 2004). Research studies usually control the content of the intervention. In practice, however, the hypnosis session would be tailored to the patient to better fit the time, place, and conditions, with reference to his or her present experience—in research terms, each case would be different. Hence the research process itself may dilute the power of hypnosis (Amundson, Alladin, & Gill, 2003; Iphofen, Corrin & Ringwood-Walker, 2005; Roberts, 2005). Clinical success is independent of precise research protocols that are rarely applied without some revisions.

To determine if hypnosis is the more effective vehicle for treatment, the researcher should compare it to other vehicles of delivery of the same suggestion (such as education, empathic or reflective listening, attention, another form of therapy). Several studies have compared hypnosis to cognitive-behavioral therapy (CBT) and to standard care practices with and without the addition of CBT. Using CBT, the therapist speaks directly to the patient's cognitive conscious mind to help effect behavior change. Hypnosis sessions are likely to include behavioral suggestions (in and out of trance), messages to the conscious and the unconscious mind at the same time, and homework. Hence, the differences between CBT and light trance hypnotherapy can be quite cloudy. A meta-analysis of 18 studies adding hypnosis to CBT to treat obesity, insomnia, anxiety, phobias, performance, public speaking, ulcers, and pain showed outcomes to be better with the addition of hypnosis for 70% of patients (Kirsch, Montgomery, & Sapirstein, 1995). Its efficacy and effectiveness will be outlined below.

Some other factors should be considered regarding research results, such as controlling for hypnotizability and for patients' past experienced with hypnosis. Highs and well-trained hypnotherapy patients have readier access to the unconscious mind and may absorb messages (as suggestions) quite deeply or literally—as they do with the placebo effect. Also, patients who are prone to dissociation or who are in severe pain or in panic may go into trance more readily. Some consideration should be given to the research outcome measure itself. We hope to help patients focus on their symptoms less, but then at the end of the study we often ask them to tune into and rate their symptoms; this could also dilute the results. Studies also need to take expectancy into consideration (Jensen & Patterson, 2005). Research shows that raising patient expectancy about hypnosis yields better clinical results; hence the patient's expectation partially predicts the outcome. We must also remember the power of the therapeutic relationship in hypnotherapy; in a research project, it is not usually

there. Bringing an outside hypnotherapist into research or psychotherapy can lead to an underestimation of the benefits of hypnosis, and S.B. Spiegel and Kahn (2001) remind us that the quality of the relationship between the treating physician or surgeon and the hypnotist can also color the outcome. This brings to mind the studies concluding that 30% of therapy outcome is based upon the therapeutic relationship, even when the treatment is medication, and that another 15% is due to expectancy (Hubbe, Duncan, & Miller, 1999).

The delivery methods of hypnosis should be considered in the design and evaluation of research, as they may vary in effectiveness. Decisions to be made include whether to use a personal versus an outside therapist, individualized versus standard protocols, or tapes, and as well as number or length of exposures and the depth of trance induced. That being said, hypnotic analgesia presented with the hypnotist in the room, individualized audiotapes prepared for the patient in private sessions, standardized audiotapes, and protocols read from a manual are all more effective than no hypnosis at all (Montgomery, David, Winkle, Silverstein, & Bovbjerg, 2002). A new format of delivery with little comparative research to date is a virtual reality presentation that immerses the patient in a three-dimensional computer-generated scenario. Virtual reality seems to fit the criteria for an absorption or trance technique. It can bring on and sustain a hypnotic state without the presence of a therapist and helps the patient escape pain or some other unpleasant experience (Patterson, Weichman, Jensen, & Sharar, 2006). While effective in burn treatment, IV placement, physical therapy, and dental work (Gold, Kim, Kant, Joseph, & Rizzo, 2006; Hoffman, Garcia-Palacios, Patterson, Jensen, Furness, & Ammons, 2006; Hoffman, Patterson, Seibel, Soltani, Jewett-Leahy, & Sharar, 2008; Sharar et al., 2007), it is not yet widely applied.

CURRENT RESEARCH AND APPLICATIONS OF MEDICAL HYPNOSIS

Medical applications of hypnosis are numerous and are more easily learned from books and case reports than from controlled research studies. Much of the current research on medical uses of hypnosis is physician driven and found in journals specific to the medical discipline and is motivated by the search for better treatment outcomes (Pinnell & Covino, 2007). The protocols widely differ according to the specific procedures and disease process (Patterson, 2004); since disorders carry their

own unique clusters of symptoms, they dictate differing lengths of treatment time, varying depths of trance, and different psychological or hypnotic approaches for healing and management. Hawkins's (2001) meta-analysis concluded that hypnosis is effective for pain related to cancer, burns, and gastrointestinal problems and for invasive medical procedures. Montgomery, DuHamel, and Redd's (2000) meta-analysis of pain analgesia studies took hypnotizability level into consideration and showed hypnosis to be effective for 75% of patients and experimental subjects, even when hypnotizability was not controlled. Hypnotic analgesia compared favorably to standard care, attention (Patterson & Jensen, 2003), and empathic attention (Lang et al., 2006).

Two journals containing best practice guidelines, research guidelines, research, and case reports are the *International Journal of Clinical and Experimental Hypnosis* and the *American Journal of Clinical Hypnosis*. Yapko (2003), Kroger (2008), Barber (1996), and Geary and Zeig (2001) have written helpful books for those who wish to add hypnotherapy tools to their psychotherapy practice, once appropriately trained. The Milton H. Erickson Foundation, the Society for Clinical and Experimental Hypnosis, and the American Society of Clinical Hypnosis offer a wide range of workshops for beginners and advanced hypnotherapists.

Chronic Pain Management

Chronic pain, as opposed to acute pain, carries the potential expectation that it will never go away and could get worse and takes a toll via both the long-term physiological stress that it causes and the associated emotional suffering that has long been identified as detrimental (Chapman & Gavrin, 1999; Ewin, 1978; Hernandez, 2009). In fact, the aspect of suffering is important enough to rate and therapeutically address separately (Hilgard & Hilgard, 1983). As discussed in chapter 17, chronic pain serves no purpose and one goal in managing it is to dismiss or disregard it as much as possible. Hypnotherapy for pain aims to disengage pain from suffering and soothe both the physical and emotional stress. Hypnotic tools include time distortion (allowing the patient to fully experience him- or herself in the future or the past), displacement (moving a sensation or part of the body somewhere else inside or out of the body in one's imagination), distortion (changing the relative size or proximity of a sensation), and altering the perception of the pain (giving it color and neutralizing the color, changing its setting on a dial, or smoothing out rough edges). Another technique involves increasing the focus

and going inside the pain sensation (thereby distorting the pain and the experience of pain, and allowing the patient to become aware of the awareness of the pain, so that the attention goes *to* the cognitive or emotional experience and *away from* the physiological sensation). The patient can also learn to self-hypnotically soothe the pain by proactively addressing the pain in a healing manner, instead of passively reacting to it (Hernandez, 2009); this alleviates suffering and powerlessness and also differentiates *who* the patient is from the stressful pain he or she is *experiencing*. Whatever tool is used, hypnotherapy itself can induce brain waves and levels of autonomic functioning that soothe the sympathetic nervous system and enhance healing and healthy resistance to disease (see Gruzelier et al., 2002, Gruzelier, Levy, Williams, & Henderson, 2001; Gruzelier, Smith, Nagy, & Henderson, 2001; all cited in Lioffi, 2006;). Brown and Fromme (1987) and Hammond (1991) provide two particularly rich resources for pain and other hypnotic techniques. Hypnotizability level of the patient and other factors partially determine which techniques will work best. Spira and Spiegel (1992) list hypnotic pain coping strategies on two dimensions, namely, the degree of pain and the patient's level of hypnotizability. This conceptualization can be particularly useful for the beginning practitioner. Whatever the technique used, patients and research subjects alike seem to get satisfaction from hypnosis sessions for analgesia even when their pain remains. When subjects were asked to list the reasons for their satisfaction with the pain hypnosis study in which they participated, 23% reported pain-related benefits and 58% reported other benefits, such as increased sense of control and positive shifts in perspective. The remaining 8% reported a negative experience, but no one reported dissatisfaction with the experience (Jensen et al., 2006). The notion that satisfaction with the patient-provider relationship may be as or more important than pain relief (Dawson, Spross, Jablonski, Hoyer, Sellers, & Solomon, 2002) seems to be in keeping with Hubbe et al.'s (1999) findings, cited above.

A review of the extensive body of literature on hypnosis and chronic pain might begin with Jensen and Patterson's 2005 comprehensive review of the techniques used according to type of pain addressed and the research techniques used (Jensen & Patterson, 2005). The types of pain include headache pain, pain related to cancer, pain caused by sickle-cell disease, low back pain, and temporomandibular (TMJ) pain. Researchers have compared hypnosis to standard medical care, advice, education, attention, the passing of time, medication, biofeedback, and other interventions. They have

taken into consideration patients' suggestibility levels and expectations, the medical complaint, frequency of treatment sessions, practice with self-hypnosis, and patients' initial treatment responses. They have found that regardless of the above variables, hypnotic analgesia is significantly more effective than any other treatment or than standard care conditions. Not surprisingly, treatments that are similar to hypnosis, such as progressive relaxation and autogenic training, showed effectiveness similar to that of hypnosis. For an extensive review of research on hypnosis for pain control, see Hernandez (in press).

Dentistry

The use of hypnosis for dental work began during World War II on the battle lines for reasons of necessity. Beyond the nerve pain of dental work, there is the potential psychosomatic element of pain in the oral cavity; the mouth is the infant's connection to the mother, the first source of gratification, and the first means of bringing attention to one's needs through crying (Kane & Olness, 2004; Thompson, 1992).

Research shows hypnosis to be relatively more effective than other approaches in quelling anxiety about dental procedures; decreasing the frequency, duration, and intensity of pain bouts during and after procedures; and reducing pain medication use (Enqvist & Fischer, 1997; Montgomery, David, et al., 2002; Moore, Bordgaard, & Abrahamsen, 2002; Simon & Lewis, 2000; Winocur, Gavish, Emodi-Perlman, Halachmi, & Eli, 2002). Hypnotic suggestions about having no pain or minimal pain are helpful, along with dissociation or deep trance, allowing the patient to avoid the dental experience altogether. One approach might be to reframe each step of the dental procedure as something positive, as is often done in perioperative preparation for surgical procedures, so that the patient views each step of the procedure as positive and helpful. For example, the sound of the dentist's drill could signify the release of bacteria or painful pressure, and the same sound could be framed as a signal to go deeper into trance. Another approach might be hypnotic age regression to encourage awareness of a pain-free or pleasantly occupied time in the past (Moore et al., 2002). Suggestions specific to anesthesia or analgesia are in order. Depth of trance, light or deep, depends upon whether or not the dentist needs to direct the patient to move or open and close the mouth during the procedure. Finally, hypnosis has also been effectively used to help patients control tooth grinding, clenching of the jaw, saliva flow, and gagging.

Headaches

Migraine, tension, and mixed headaches all respond beneficially to hypnosis (Elkins, Jensen, & Patterson, 2007; Hammond, 2007). Research shows that frequency, duration, and severity of migraine episodes decreased even after one group hypnosis session that was followed up with 12 weeks of hypnosis audiotapes (Emmerson & Trexler, 1999). Different headaches respond to different suggestions. Guided imagery audiotapes improve tension headache pain, vitality, and overall mental health (Mannix, Chandurkar, Rybicki, Tusek, & Solomon, 1999). Suggestions to directly or indirectly relax the whole body system or the head area help tension headaches; for example, the patient can imagine breathing through the scalp, through the hair, warming the scalp, or enjoying a warm beach. Hammond (2007) advises patients to use self-hypnosis at night to prevent tension headaches in the morning. A migraine patient may imagine hiking in snow, having an ice pack on this or her head, or tightening up the blood vessels. These suggestions point to the importance of carefully interviewing your patient to find out the specific problems he or she is having so that your hypnotic session is tailored to his or her needs.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a common source of pain. Most people with IBS have a combination of abnormal autonomic nervous system functioning and a low threshold for bowel pain (Palsson, 2006). Hypnotherapy improves the autonomic symptom dysfunction as well as the pain (Simrén, Ringström, Björnsson, & Abrahamsson, 2004) for years after treatment (Gonsalkorale, Miller, Afzal, & Whorwell, 2003). There are two major protocols for hypnotic treatment that have been found to be consistently effective for treating the physical symptoms of IBS as well as the accompanying depression and anxiety (Gonsalkorale, Houghton, & Whorwell, 2002; Gonsalkorale, Toner, & Whorwell, 2004; Lea et al., 2003; Whorwell, Prior, & Faragher, 1984). Palsson, Turner, Johnson, Burnett, and Whitehead's (2002) protocol shows approximately 50% pain reduction on a daily basis. The benefit of the protocol is that it is carefully scripted to be administered word for word by other therapists. A study comparing the scripted protocol (Palsson, 2002, 2006) with the same protocol administered with a slightly individualized presentation showed little difference in success rate (Barabasz & Barabasz, 2006). Both protocols include sessions with the therapist plus home audiotapes with suggestions for gut

comfort and relief of symptoms, general relaxation, self-efficacy, self-control, and dissociation from the pain. Whorwell et al. (1984) also suggest transferring warmth from the hands to the gut.

Perioperative and Procedural Use

Minimizing physical and emotional pain before, during, and after surgery can improve healing and reduce length of hospital stay and amount of pain medication used and can make for happier patients and surgeons (Kessler & Dane, 1996). Even though hypnotic analgesia was successful for centuries, perioperative use in the 1990s met with resistance primarily due to difficulties billing for therapists' time. Now there are adequate mechanisms in place for reimbursing psychologists for time spent on pain and disease management. In fact, some health insurance companies now require pre-surgical psychological screening before certain surgical procedures are approved for reimbursement. Preparation for surgery can be done in one session on the day of surgery or it can be done in private practice by psychologists familiar with the surgery to be performed (Massarini, Rovetto, & Tagliaferri, 2005). The process has a positive impact on surgical anxiety, blood pressure, and sense of control (Hart, 1980); pain, edema, inflammation, and post-surgical anxiety (Cupal & Brewer, 2001); blood loss, wound healing, nausea, and vomiting (Gurgevich, 2003); length of hospital stay and use of IV pain medication in the hospital (Lobe, 2006); and both objective and subjective measures of surgical healing (Ginandes, Brooks, Sando, Jones, & Aker, 2003). A meta-analysis showed that patients prepared hypnotically for surgery do better than 89% of other patients, regardless of manner of presentation (Montgomery, David, et al., 2002). Positive psychological benefit is related more to the expectancy ratings of treatment success after the initial session than to number of additional sessions or to hypnotizability (Jensen et al., 2005).

Hypnotic analgesia was useful during surgery when it was the only anesthetic and there were no alternatives; now it is most often used in addition to other anesthetics or analgesics. If it is used alone, there should be a good reason for its sole use and the patient should have a high expectancy of success and a high level of hypnotizability (Montgomery, Wertz, Seltz, & Bovbjerg, 2002). One should stringently test for hypnotizability (see Lynn, Council, & Green, 2003; Weitzenhoffer & Hilgard, 1963), as a very deep, long trance and high expectancy are important. Perioperative preparation can be done with any level of trance, even conversational trance (Dyas, 2001; Kessler et al., 2002).

Kessler (personal communication, 1996), who has much experience in this arena, feels that the most important factor in determining the need for pre-surgical preparation is whether or not the patient has negative expectations about surgical experience and outcome arising from previous experiences that either he or she or those close to him or her have had. Primary goals are to promote positive expectancy of the surgical outcome, and to put postsurgical pain into proper positive perspective. The therapist will want to reframe the surgical process in detail in a positive light, assuming that even under total anesthesia there is some level of awareness in every patient—for example, “When you feel a very cold sensation on your belly, it will indicate that the nurse is sterilizing the area to keep you safe from any infection,” “When you feel your doctor touch your stomach with her instrument, then you know that she has found the smallest opening to get to the area where she will fix the problem,” and “When you feel a little pulling, you know that she is closing the area.” The therapist can suggest that the patient look forward to a favorite meal just after waking up, to promote peristalsis, or look forward to some postsurgical pain as an indication that the nerves and skin are in the healing process. The patient can be encouraged to go immediately and completely in his or her imagination to an enjoyable place and to stay there, to “only listen to comments during surgery that begin with your name and that come from your surgeon,” and to know that “when you hear people calling you by name, it is time to awaken.” When there is acute pain during procedures and after surgery, the patient’s focus can be directed away from the experience, and the experience can be reframed as beneficial, healing, and not to be feared.

Burns

Ewin (1986a, 1986b), a teaching surgeon and psychiatrist who uses hypnosis during procedures and surgery, has also used hypnotic imagery to prevent symptom formation in newly burned patients. He offers suggestions to counteract heat and the body’s response to the burn (including sun burns), such as reddening and blistering, as soon as possible after the burning incident. Suggestions include swimming in a cool stream, placing one’s hands in a pan of cold water, cleaning a prized fish, holding an ice cream cone, or walking in a rain forest. This may prove to be particularly useful for first aid and emergency situations. In fact, hypnosis may be used in emergency rooms to limit trauma and fear related to sudden bouts of serious pain.

The use of hypnosis for third-degree burn pain, which can be very intense for an extended period of

time, has a relatively long history of success (Frenay, Faymonville, Devlieger, Albert, & Vanderkelen, 2001). Wound care requires frequent debridement of the area, often for a very long time; short of sedation, medication often does not cover the pain. Immersive virtual reality has also proved to reduce pain and anxiety and was reportedly enjoyable for those using it during wound care (Patterson et al., 2006).

Since the pain of wound care and healing is acute, patients can benefit from displacing the injured part of the body to another location and engaging in a different activity; they can imagine analgesia or anesthesia, or being somewhere else entirely. For the negative anticipation of upcoming debridement sessions, suggestions for time distortion, amnesia for parts of the debridement session, and possibly amnesia for parts of the traumatic injury itself might be helpful. Patients may also want assistance adjusting to disfigurement and disability, which can be addressed with suggestions that reframe the experience and encourage flexibility, acceptance, self-confidence, and competence.

Osteoarthritis

The aging population may appreciate self-hypnotic techniques to counteract arthritic pain and to keep active. Goals are to counteract stiffness and pain. A study found hypnosis to be more effective than relaxation therapy for arthritis (Gay et al., 2002). Potentially helpful suggestions, depending upon the patient and situation, include age regression to an earlier, pain-free time; imagery of moving through warm water; feeling warm blankets or sunlight; and any activity (floating or even ballroom dancing) that suggests flowing effortlessly. The therapist might also suggest focusing on a higher plane to stay goal directed, self-caring, and self-respectful in order to counteract focusing on the pain or on fears or concerns about aging. There is some speculation that anger and defensiveness are related to arthritis and can lead to muscle tension and stiffness; thus suggestions that address flexibility and contentedness might help. Hypnosis can also reduce stress through direct and indirect suggestions to relax and through enhancement of patients’ sense of self-efficacy and self-control.

Cancer and Palliative Care

Cancer and other potentially terminal conditions are clearly about more than just pain, although pain might be a significant factor. End-of-life issues include grief, depression, anxiety, fear, loneliness, and regret. Nausea and vomiting, frequent side effects of cancer treatment,

respond well to hypnosis. There is also a link between physical and emotional stress and taxation on the immune system, which can hinder recovery time and lower resistance to secondary illnesses.

D. Spiegel and Bloom's hallmark study published in 1988 showed that terminal cancer patients who engaged in hypnotherapy had slightly longer life spans. When the study was redone in 2007, the same effects did not hold, possibly because by 2007 much better medical treatments for cancer were already extending the life spans of all but the most seriously ill patients (D. Spiegel et al., 2007). Hypnosis has been shown to be more effective than CBT for cancer-related anxiety and stress (Lioffi & Hatira, 1999; Montgomery, Weltz, et al., 2002; Mundy, DuHamel, & Montgomery, 2003), for cancer-related pain (Marcus, Elkins, & Mott, 2003), and for pain related to bone marrow transplants (Syrjala, Cummings, & Donaldson, 1992). Many quality-of-life measures, including anxiety and stress, can be improved with the use of self-hypnosis in patients experiencing cancer (Classon et al., 2001; Laidlaw, Bennett, Dwivedi, Naito, & Gruzelier, 2005; Laidlaw & Willett, 2002; Lioffi & White, 2001). Spira (1997) outlines uses of hypnosis to support patients' and their families' existential, religious, and other beliefs about life after death, which can be satisfying and comforting to their treatment teams as well.

HYPNOSIS IN PSYCHOTHERAPY

Anxiety

Hypnotherapy is effective for treating many forms of anxiety (Weisberg, 2008). Current research shows higher levels of hypnotizability in people who are diagnosed with anxiety disorders, including PTSD, acute stress disorder, and dissociative disorders (Bryant, Moulds, & Guthrie, 2003; D. Spiegel, Hunt, & Dondershine, 1988; Stuntman & Bliss, 1985). Highs with PTSD had relatively more avoidance responses remaining after treatment (Bryant, Guthrie, Moulds, Nixon, & Felmingham, 2003) but had relatively fewer stressful thoughts related to PTSD or their acute stress (Bryant & Wimalaweera, 2006). When hypnosis was added to CBT for treatment of PTSD and compared to supportive therapy, the CBT with hypnosis group had better treatment results than the other two groups (Bryant, Moulds, Guthrie, & Nixon, 2005). Patients with public speaking anxiety got better treatment results with hypnosis than with CBT alone (Schoenberger, Kirsch, Gearan, Montgomery, & Pastyrnak, 1997). Panic attacks may also involve dis-

sociative states, in that the sufferer's worst fears are not usually occurring at the time they have the panic reaction (Krystal, Woods, Hill, & Charney, 1991). Those who dissociate under stress are likely to be higher in hypnotizability, but the meaning of that relationship is unclear, and the research is mixed as to whether or not those with higher hypnotizability get better treatment responses.

There are several ways use hypnosis to approach anxiety. Suggestions about the anxiety-producing situation offered while the patient is relaxed can help neutralize the physiological component of the usual anxiety state; one cannot feel relaxed and anxious at the same time, and if the patient thinks of the trigger to anxiety while being relaxed, he or she decouples the thought from the anxious physiology. The therapist can suggest that the patient use a positive hallucination to neutralize upcoming anxiety attacks (such as feeling a guardian angel on one's shoulder, or seeing a feared audience as silly or less knowledgeable). The patient can learn to distort time such that the exposure to the threat is short and the focus is on how he or she will have resolved the situation (future time distortion). He or she can learn to tune in to other aspects of the event or distort the aspect that was anxiety provoking ("Imagine your neighbor coming in and out of a cuckoo clock as she is yelling at you"), learn a soothing mantra or a positive affirmation to say during upcoming exposures, or embed a trigger to go into a state of relaxation when the exposure next occurs. In self-relations psychotherapy (Gilligan, 1997), the patient learns intrapsychic self-management, in which he or she identifies and differentiates (1) the situation outside him- or herself from (2) the part of him- or herself that is afraid and from (3) his or her adult cognitive mind. The patient learns to strengthen the internal connection between those two parts of him- or herself with supportive and controlled internal conversations (see Hernandez, 2002). Self-relations psychotherapy allows patients to work with themselves internally, bringing their best skills to the situations they fear; it also generalizes nicely to other stressful situations, including pain management (Hernandez, 2009).

Therapists can also use hypnosis to give the effect of in-vivo desensitization so that the patient does not have to leave the office or expose him- or herself to embarrassment or harm. Within the trance, the therapist can suggest the transitional process by which the patient will gradually proceed to develop better coping mechanisms for managing fear. The projected screen technique is also helpful for counteracting fear. With that technique, the trance suggestion is that the patient and the therapist are watching a movie of the event that

the patient fears, or a small TV showing the event, from a balcony together. Suggestions can then be made to make the picture fuzzy, farther away, muted, or otherwise altered to reduce the anxiety related to it. Hence, the therapist can help control the intensity of the experience to fit the patient's tolerance level and can therapeutically suggest the optimal alterations to the image and responses. The therapist can also suggest negative hallucinations to help the patient visualize the fear trigger with some threatening component missing. A posthypnotic suggestion can enhance continuing improvement and success with the change, so that the patient can handle the event in the future without dwelling on it. Suggestions that boost competence and confidence help to prevent negative anticipation that future panic could lead to trouble or embarrassment. In fact, it is always good to add a posthypnotic suggestion about continued improvement in the future, and possibly for acceptance of what the patient cannot change.

Hypnotic and metaphoric stories may be quite useful in addressing patients' problems, one at a time or several at a time. For example, there may be one story about someone in a dilemma similar to the patient's that resolved itself nicely, a story about how someone gathered problem-solving skills similar to the ones the patient will need, a story about how someone gained self-confidence that the patient is lacking, and perhaps ones about animals who have the inherent traits or strengths that would be helpful to the patient. Such stories may involve (or lead to) deeper trances so that the right brain can translate these metaphors without the interruption of the conscious mind. This technique can be effectively used in brief therapy sessions.

Depression

Primary care physicians often are the first clinicians to encounter depression in a particular patient, and medication is often the first line of treatment, followed by CBT or interpersonal therapy. There is a wide body of research showing that they are effective and that prescribing or finding a CBT therapist may take less time than finding a hypnotherapist. Of course, various forms of depression, such as major depression, bipolar disorder, atypical depression, and some somatoform or pain disorders and adjustment disorders, require different approaches and set up varying degrees of alarm. In addition, depression may also be caused by something such as a loss or other negative situation that one cannot always change but that must be addressed. Often more than one form of therapy, including counseling, is necessary.

A recent study showed cognitive hypnotherapy to be more effective than CBT for symptoms of depression, anxiety, and hopelessness after 4 months of treatment and at 6- and 12-month follow-ups (Alladin & Alibhai, 2007). Another showed it to be effective in treating postpartum depression when the reasons behind the depression were also addressed (Yexley, 2007). Hypnosis also resolved depression concurrent with nicotine abuse better than behavioral counseling did (Carmody, Duncan, Simon, Solkowitz, Huggins, Lee, & Delucchi, 2008), and it effectively improved hair growth, depression, and anxiety in alopecia patients (Willemssen & Venderlinden, 2008).

Depression can affect emotions, cognition, and physiology simultaneously, and hypnotherapy can address them simultaneously. Hypnotherapy can give the patient and therapist access to the unconscious causes and mechanisms of the depression, bypassing the negative mind-set, revising automatic and habitual negative thoughts, increasing tolerance for ambiguity, and improving decision-making strategies (Yapko, 2006). Yapko (1992, 2001, 2006) has written comprehensively on how, why, when, and with whom to use hypnosis to treat depression.

Alladin (1992, 1994) describes the use of hypnosis in conjunction with CBT in the cognitive dissociative model of depression, addressing all the cognitive and somatic aspects of the disorder. CBT takes advantage of the reasoning elements of cognitive restructuring to change thinking patterns and behavior, while hypnosis takes advantage of access to the unconscious mind to explore the subjective aspects of the depressive experience and effect change starting with the subjective experience itself (Alladin, 1994). Alladin (2006) uses ego-strengthening suggestions, as well as concrete suggestions to use self-hypnosis tapes and to focus on positive thoughts and successes. Yapko (2006) points out that hypnosis can help patients go back in time to understand how their thinking became negative and what spawned the hopelessness. The treatment, then, extends from the inside, at the level of memories and beliefs, on outwards to change attitudes and behaviors. In two books for lay audiences, Yapko (1997, 1999) points out to patients that through their thinking and subsequent behavior, they are indeed depressing themselves. Such books can be helpful adjuncts to therapy.

Hypnosis with Children

In general, children are more hypnotizable than adults for a number of reasons. They have much richer fantasy lives, are relatively more curious, and are encouraged

to use imagination in play. They also have fewer fixed interpretations of the world and are relatively trusting of adults and authority. Peak hypnotizability may be as late as latency (8–12 years of age), when children are the most open minded, curious, imaginative, and willing to suspend judgment, and when they are reasonably knowledgeable. Critical thinking develops as the brain matures; in adolescence, society demands more of it. As children are not reflective thinkers, they are more likely to be psychosomatic in presentation of emotional or situational problems. The bank of literature on childhood stomachaches tells us that for them, stomachaches may be a benchmark for distress that may otherwise go unexpressed.

Learning pain management and self-control early via self-hypnosis can help children tolerate medical procedures (shots, fracture settings, etc.) and eliminate many negative associations that may remain with them as adults. Studies show that children benefit from self-hypnosis training to reduce functional abdominal pain (Anbar, 2001); pain and anxiety during lumbar punctures (Liossi, White, & Hatira, 2006) and acupuncture (Zeltzer, Tsao, Stelling, Powers, Levy, & Waterhouse, 2002), headache pain (Kohen & Zajac, 2007), and stress related to urological procedures (Butler, Symons, Henderson, Shortliffe, & Spiegel, 2005) and to improve respiratory functioning when they are anxious (Anbar & Giesler, 2005). In general, hypnosis in some situations is more effective than simple distraction (Liossi & Hatira, 1999; Wall & Womack, 1989) or CBT (Zeltzer & LeBaron, 1982).

Designing trances or trance experiences for children involves taking their developmental age into consideration, as well as the degree of trauma and fear they experience. Children are easily traumatized from a very early age, but at the same time they respond to being soothed with touch and sound and a gentle voice. They are familiar with storytelling and songs, puppets and role-playing with dolls and animals, which become subjects and vehicles for therapeutic metaphors and stories, and children respond well to stories about magical travel and games. Olness and Gardner (1988) recommended framing therapeutic suggestions in familiar contexts such as bubbles, pop-up books, and familiar places and movie or book characters. Bouncing balls, yo-yos, pendulums, and coin dropping may be used for inductions. Following developmental interest, adolescents and older children respond well to stories and images about peer groups and relationships. For pain control, children may be relatively accepting of therapists' suggestions to "go inside and turn down the pain dial in your head." One can follow play therapy guidelines for age-appropriate

language, voice tone, and interlacing conversation with play (Olness & Kohen, 1996).

Habit and Addiction Control

Smoking cessation may come to mind first in regard to hypnosis for health-compromising habits. Some programs advertise success rates as high as 90%, while others report rates of 15% and lower. There is greater potential for success when patients attend several treatment sessions, reduce the temptations to smoke by changing environmental cues, have internal motivation, and are ready to stop smoking; when hypnotizability is taken into consideration and hypnotic suggestions are tailored to correspond to the patient's cues to smoke; and when individualized relapse prevention cues are included in the hypnotic protocol. The patient who says, "Just hypnotize me and make me stop smoking," may have a poorer prognosis for success.

Other factors to be considered are the extent of nicotine dependency (some clients smoke so heavily that immediate cessation is risky), and underlying anxiety or depression that the smoking is masking needs attention. In general, health behavior changes when patients recognize that their behavior is unhealthy, they themselves are at risk, cessation is possible, and it is better than any other alternative. In fact, a hypnotic session could help the patient confirm those beliefs. Before quitting, patients should be made aware of the dangers of smoking in concrete terms, perhaps with pictures of smokers' diseased lungs. They might also be told that thoughts and needs are different than cravings, which are psychological or emotional ("When you feel the craving you used to respond to so often, it is an indication that the nicotine, not your will, was driving your behavior"), and that the anxiety experienced during the craving cycle is artificially created by substance use. They should know that cravings are short and will diminish in frequency when abstinence is accomplished. The desire to smoke may be still there and should be addressed with suggestions about relapse prevention.

A recent study showed 40%–60% success rates with total cigarette abstinence at 3- and 6-month follow-ups (Elkins, Marcus, Bates, Hasan Rajab, & Cook, 2006). The practitioners included in their program (1) multiple sessions, (2) suggestions to practice self-hypnosis, (3) individual counseling sessions with a seasoned hypnotherapist, and (4) individualized hypnotic protocols. In another study in which either hypnosis or behavioral counseling was added to prescription of nicotine patches, the addition of hypnosis was more effective than the behavioral counseling for both smoking cessa-

tion and relapse prevention (Carmody et al., 2008). In their hypnotic protocols, Elkins, Marcus, Hasan Rajab, Bates, and Cook (2007) include imagery for relaxation, cues to dissociate from cravings, and imagery of the positive outcomes of cessation. Geary (2008) uses a sequencing technique that begins with a detailed patient interview, so that he can record the patient's physical and emotional feelings and thoughts, moment by moment, through needing, thinking about, lighting up, and smoking a cigarette. Then, in their trance, he reframes their sensations and substitutes healthier ways to satisfy each sensation in turn—for example, “When in the middle of the morning you begin to feel a little jittery, that can be a signal that you are ready to take a break and step outside the front door of the building (not the area where smokers gather) to take a deep breath of clean air and feel the exhilaration running through your system,” or “When you finish your dinner and wonder what to do next, that will be the automatic trigger to sit on the porch with a cup of coffee (or take a walk).” Geary also emphasizes success, the individual's new image as a non-smoker, self-confidence, self-control, and relapse prevention.

Controlling eating habits that lead to obesity or other health problems involves managing rather than ignoring unconscious cues to eat. As the rates of obesity in the United States are around 30% and the ramifications to health are many, the need for treatment spans many disciplines, including cardiology, orthopedics, and sleep and diabetes care. Obesity related to genetics, medication, or inability to exercise may still require attitude or behavior adjustments. How one eats is often deeply rooted, and the foods that lead to health problems are often addictive. Losing weight is a slow process requiring patience and dedication. Hypnotic protocols and suggestions can address all the above, excluding genetics. One goal is to help the patient modify preferences and priorities. Once a good weight and diet are established, patients can benefit from posthypnotic suggestions for enhancing self-esteem and self-control. Again, understanding the psychological nature of cravings versus hunger is important.

Adjunctive use of self-hypnosis tapes is particularly helpful between sessions for patients who want to manage relapse triggers and anxiety or depression without abusing substances. In general, self-hypnosis tapes in therapy programs can determine success in changing and improving self-image, but Highs are more likely to use tapes than Lows are, and hypnotizability is directly related to use of prescribed self-hypnosis tapes (Pekala, Maurer, Kumar, Elliott, Masten, Moon, & Salinger, 2004).

OVERVIEW OF HYPNOTIC TECHNIQUES

Stages of the Hypnotherapy Session

The usual hypnotherapy session consists of four stages—first, an induction to lead the patient into trance, then a period of deepening involvement of the unconscious mind while minimizing involvement of the conscious mind, then the therapy itself, and finally a guided transition back to conscious awareness. During a pretreatment assessment, the therapist should learn the patient's perceived problem; his or her history, ability to reflect, desired level of participation, past experience with hypnosis, religious beliefs regarding trance, interests, and past and current life experiences; any traumatic events that may have involved dissociation; and the patient's language style. The last piece of information will help the therapist choose the words, metaphors, and story content to use during therapy. Usually, the more the trance is in synchrony with the patient's internal experience at that time, the more effective it is likely to be.

Remember that the hypnotic suggestion must get to the unconscious mind in one of three ways: (1) directly to the unconscious mind while the conscious mind is in deep trance, (2) indirectly to the unconscious mind by confusing the conscious mind or using another subliminal technique, or (3) from the conscious mind, either reflectively or by self-hypnosis. Style of hypnosis should vary according to the therapist's strengths, personality, and judgment about the patient's needs and abilities, as well as the therapeutic environment. Duncan, Miller, and Sparks's (2004) research shows that all therapy techniques work relatively equally well; the most effective therapy seems to be the one the therapist feels most comfortable using. Also important are the therapist's consideration for the patient's chosen outcome, and his or her flexibility in changing approaches as the patient's needs change (Miller, 2008).

The hypnotized patient is suspending vigilance and giving over access to his or her unconscious mind, so he or she is particularly vulnerable. Hence hypnotherapists must be properly trained and comfortable with the therapeutic issues they are addressing and monitor how the patient is doing before he or she leaves the office. The latter is particularly important with highly hypnotizable, traumatized, or depressed patients. Beyond that, the allotted time of the session and the depth of trance necessary can vary.

The literature suggests that deep or formal trances are not always necessary for patients to achieve benefit

from hypnosis, and that we can speak to the unconscious mind without formal trance (Haley, 1986). Many hypnotherapists use light trances to work with patients' unconscious processes, and there is some literature on the use of conversational trances (Kessler et al., 2002). Even establishing very good rapport with the patient will lower his or her vigilance, so that any comments land closer to his or her core. Neurolinguistic programming, which developed from the study of how the unconscious mind works, takes advantage of all levels of hypnotic trance including conversational trance. A large part of neurolinguistic programming's focus is on developing a rapport with patients to help them make changes that parts of their minds are resisting (see <http://www.NLPU.com> for more information). Some situations are best handled when the patient can verbalize what he or she is experiencing or processing, and some medical procedures require the patient to report what he or she feels. In such cases, a light trance may be in order. Lighter trances also allow patients to learn self-hypnosis during therapy.

Although hypnotizability is a trait, under certain conditions, such as experiencing or recollecting trauma or while dissociating, patients may already be in some level of trance. Also, seasoned hypnotherapy patients will likely go into trance easily or even on self-command, and some who are more right than left brained may access the unconscious mind easily with less induction. In the ER or at the scene of an accident, a victim or bystander may be stunned or in some level of shock, and a quick, direct approach to induction—even telling the patient to go somewhere else in his mind *now*—may be useful.

Patients may unexpectedly come out of trance when they experience something uncomfortable or when they have an insight; other times, a noise may interrupt the session. Coming out and going back into trance can sometimes deepen the trance (this is called fractionation), and therapists can use it to their advantage to learn about the patient's internal experience.

Preparation for the Therapist and for the Patient

Professionals should be thoroughly trained before using hypnosis and should work only in areas of their professional expertise. The American Society of Clinical Hypnosis and Society for Clinical and Experimental Hypnosis train and certify health and mental health care professionals in hypnotherapy. Training includes lectures, readings on ethics and techniques, practice

sessions, and a period of supervision. It also brings up legal considerations to keep in mind, such as the potential for accessing false memories through hypnosis.

Patients' preparation for hypnotherapy includes dispelling the common myths about what hypnosis is and is not, giving information about what they might experience, making sure that hypnosis is not against their religious beliefs, and advising them to stop the session when they need to. This protects all involved. They should also be reminded that all hypnosis is self-hypnosis and that susceptibility is independent of intelligence.

For the benefit of positive expectancy, just using the word "hypnosis" may benefit the patient outcome. This may be particularly true for the patient who would like someone or something else to do the work for him or her. Such a patient may be more willing to suspend vigilance, but on the other hand, research shows that patients achieve better pain control when they attribute it to themselves rather than to the therapist (Spinhoven, Linssen, van Dyck, & Zitman, 1992). Nonetheless, the therapist and the treatment staff's positive expectancy also seems to improve the success of hypnosis (Jensen & Patterson, 2005).

When possible, a quiet, pleasant, and emotionally safe space is the best venue for hypnosis. Patients may do best when sitting with both feet on the floor and with hands resting on the knees, so that they are not likely to fall asleep and so that they do not have to work at balancing. However, hypnosis done in an unexpected place may carry an element of surprise that can be beneficial. Therapists can always tailor their techniques according to their setting, even in busy clinics.

Inductions

The purpose of the induction is to suspend the patient's vigilance, narrow his or her attention, and engross him or her while the therapist either suggests dissociation from the conscious mind or speaks directly to the unconscious mind. Examples of classic hypnotic inductions are the following: arm catalepsy (the patient holds his or her arm out until he or she loses the feeling that it is there or can no longer move it, and then the patient may go into trance); chiasson induction (the patient holds his or her hand out, and as it moves toward his or her face and touches the face, the patient descends to the bottom and drops into trance); coin technique (the patient holds a coin out at arm's length, and when he or she drops, he or she may drop into trance); descending a staircase (the patient envisions going down a staircase and counting the steps one by one until he or she drops

into trance); eye fixation (the patient focuses intently on one point until his or her eyes close and he or she goes into trance); imagery induction (the patient visualizes a wonderful, soothing place, smelling, hearing, and feeling the place); magnetic hands (the patient holds his or her hands out in front of him or her; when they come together, the patient drops into trance); pendulum technique (the patient swings a small pendulum in front of him or her at eye level; when his or her arm tires and the pendulum drops to the table, the patient goes into trance); the eye roll (the patient takes a deep breath in and rolls the eyes upward to look into the eye sockets, and as he or she closes the eyes and slowly breathes out, he or she goes into trance); and the reversed arm levitation induction (the patient holds his or her arm out and slowly lowers it; when it reaches his or her lap or the table, the patient goes into trance).

Other inductions may occur conversationally, with the therapist slowing his speech and speaking slower and more quietly, boring the patient into trance, confusing him or her, or inviting the patient to focus inside his or her body. Chanting or spinning can also lead to trance. A lighter trance takes less induction time or planning than, for instance, a deep trance used in place of anesthesia during surgery. An experienced hypnotherapy patient may need little or no formal induction; he or she may be invited simply to do what is he or she needs to do to go into trance. The therapist's speech and word choice can ensure a smooth transition into the deepening phases and actual therapy, wherein the patient can experience feeling better; learn new tools, attitudes, or ways of thinking or being; forget; reframe; change a perception or put it into perspective; or view sensations constructively.

Suggestions

Curiosity and imagination can be essential keys for change—where the mind goes, behavior and physiology may follow. Hypnotic suggestions ideally bypass conscious vigilance, so that suggestions such as “Feel yourself within a circle of heavenly white light that insulates you from all harm” and “Paint a large see-through bubble around yourself” are not scrutinized for logic. Stories and metaphors, careful wording, and verb tenses can also be suggestions (for example, gerunds can be used to suggest ongoing change and flow, the past tense can be used to indicate that change has already taken place, and future tense can be used to indicate that change will happen). Suggestions can be direct or indirect—for example, the therapist can lead the patient to progressively relax muscles versus suggesting that he

or she imagine lying on the beach of a peaceful island, which would also warm and relax muscles. With direct suggestion, the patient can imagine (“feel”) the warm blood flowing through his or her system. Indirectly, the patient might proactively send a warm beam of light from the heart down through his or her arm all the way to the fingers. Encouraging vivid imagery of the desired change state helps the patient experience all aspects of the desired situation, for example, imagining being on, seeing, hearing, and smelling a warm beach. Imagining heat can increase blood flow, which can relax muscles, and vice versa. If the therapeutic goal is to handle flashbacks or blur a memory, the suggestion can be to see the scene in question on a projected screen, or from above, in black and white, and then out of focus on the screen. Research shows that encouraging mental rehearsal at times after the session can help mental and physical performance. Emphasizing curiosity and offering paradoxical assignments (for example, “Go for a walk on the beach, where the answer will come to you,” or “Put a special rock under your bed just under your heart, and your dream will show you how to gain strength”) can help the patient open the mind to be resourceful in finding the answers within. Vagueness is also useful; when the patient fills in the blanks with his or her own images and words, they are more likely to be relevant to him or her and useful in subsequent self-hypnosis sessions. Therapists can create a state of boredom to lead the patient into trance, create confusion by misspeaking, and embed suggestions in a conversation.

Ending the Session

To bring the patient out of trance, the therapist may encourage more cognitive thought and less unconscious processing, suggesting that the patient recall the time, day, current weather and season, or the temperature of the room. The therapist can raise the volume and pitch of his or her voice, speed up speech, and call attention to the fact that it is he or she, not the patient's internal voice, who is speaking to the patient. If the induction involved walking down a staircase, then the reverse process—having the patient come back up the staircase—would be used to bring the patient out of trance. There are often lingering side effects to trance that are not convenient, such as foggy thinking, lethargy, disorientation, slow heart beat, lack of vibrancy, and temporarily losing track of what he or she was thinking about before the trance. These side effects may be erased with another brief series of suggestions so that the patient feels refreshed and in control at the end of trance.

Posthypnotic suggestions are commonly used to optimize therapeutic gain. They may be cues or triggers for the patient to go into a relaxation state, avoid a habit, or remember something specific—for example, “Over the next week as you begin to get ready for bed (or come home from work), it will become easier and easier for you to remember to do your exercises.” Suggestions can be designed for relapse prevention (“The sight of a cigarette will automatically remind you of the pictures of smokers’ lungs that you saw today”). Whenever possible, the therapist can add suggestions to enhance self-confidence and a sense of well-being.

Naturalistic Approaches

Milton Erickson’s approach to hypnotherapy stemmed from his belief that his patients were unique and could be resourceful in resolving their own pain and suffering if they were guided in the right direction and believed in themselves. He oriented patients toward positive change primarily by using indirect suggestions that bypassed the conscious mind in conversation, or by using stories about others. His inductions guided the patient to intrinsically find answers to his or her own problems. He created cooperative and interactive trances wherever possible, such that his hypnosis sessions often appeared to be formal hypnosis. He gained rapport by carefully watching and listening to the patient, matching or accepting the patient’s mood, words, and thinking patterns. Erickson stressed the importance of understanding how the problem the patient currently had was actually a solution to an earlier or a bigger problem; this was to be welcomed and addressed with curiosity. He often reframed the problem in more workable terms, seeing the problem from a different perspective. He used in his inductions, for example, including syntactical errors in conversation; speaking in paradoxes; using strange wording; or putting two opposing, contradictory, or unrelated ideas in the same sentence. Messages could also be hidden in a sentence about something else, or slid in under the distraction of humor. See C. Lankton and S. Lankton (1989) and Kane and Olness (2004) for examples of Ericksonian metaphors and stories. See Haley (1986) for examples of Erickson’s therapy.

CONCLUSIONS

Trances are natural phenomena, and hypnotists and hypnotherapists have been guiding patients into them for over 200 years. The surge of brain and other central nervous system research as to what hypnosis is and

how it works has given credence to the reasons why it should be used. Medical and hypnosis researchers have shown us how, when, and where it can best be used. Even in the wake of improved medications and the advances of other psychotherapy methods, hypnosis is assuming an increasingly respectable role in psychology and in medicine. There are additional benefits to studying hypnosis: you may use self-hypnosis in many walks of your own life, and you will surely enhance your understanding of the primary and secondary processes of the mind. Both these may work as skeleton keys for doing more effective psychotherapy.

Behavioral Cardiology: Integrative Approaches to the Treatment and Management of Cardiovascular Risk Factors and Disease

Teresa M. Edenfield

Cardiovascular disease (CVD) is a major cause of morbidity and mortality in industrialized countries and worldwide (Burt et al., 1995; Joint National Committee, 2003; Reddy & Yusuf, 1998; Rozanski, Blumenthal, Davidson, Saab, & Kubzansky, 2005). Hypertension (HTN), or chronically elevated blood pressure, is a prominent cardiac risk factor that affects approximately 50 million Americans (Burt et al., 1995; Joint National Committee, 1997). HTN alone places affected individuals at elevated risk for various CVD conditions such as stroke, myocardial infarction (MI), and congestive heart failure, as well as renal failure, peripheral vascular disease, and cognitive impairments that may be reversible with treatment (Blumenthal, Madden, Pierce, Siegel, & Appelbaum, 1993; Waldstein, Manuck, Ryan, & Muldoon, 1991). It is widely accepted that behavioral factors such as smoking cigarettes, unhealthy eating be-

haviors, and a sedentary lifestyle contribute to the development and maintenance of CVD and associated risk factors (e.g., HTN, obesity). These, as well as other traditional risk factors, including diabetes and family history of CVD, are estimated to account for 70%–80% of all coronary artery disease (CAD) risk (Davignus et al., 2003; Emberson, Whincup, Morris, & Walker, 2003). Psychosocial risk factors such as psychological disorders (e.g., depression, anxiety, bipolar disorder, schizophrenia) and socioeconomic challenges are also widely known to contribute to higher risk and poorer prognosis relative to CAD (Everson-Rose & Lewis, 2005; Frasure-Smith & Lesperance, 2005; Ramachandruni, Handberg, & Sheps, 2004; Rowan, Haas, Campbell, Maclean, & Davidson, 2005; Rozanski et al., 2005; Rutledge et al., 2004; Sowden & Huffman, 2009; Strike & Steptoe, 2004; Todaro, Shen, Niaura, Spiro, & Ward, 2003). Despite

growing evidence that psychosocial risk factors play an important role in treatment outcomes relative to CVD, they are often overlooked in research investigating risk and prediction of related medical conditions. Behavioral cardiology is a complex field that grew out of the need to address these issues and may be defined as the study and application of psychosocial factors in the assessment and reduction of CVD risk (Thomas, 2005).

Depression has long been identified as one of the strongest negative psychosocial risk factors for CAD (see Barth, Schumacher, & Hermann-Lingen, 2004; Glassman & Shapiro, 1998; Hemingway & Marmot, 1999; Musselman, Evans, & Nemeroff, 1998; Rozanski, Blumenthal, & Kaplan, 1999). Numerous studies over the past 40 years have shown that depression may significantly increase the risk of morbidity and mortality in individuals with CVD (e.g., Frasure-Smith & Lesperance, 2006; van Melle, de Jonge, Spijkerman, Tijssen, Ormel, van Veldhuisen, & van den Brink, 2004). An estimated 50% of survivors of MI have been found to demonstrate significant symptoms of anxiety and/or depressive disorders (Lane, Carroll, Ring, Beevers, & Lip, 2001). Moreover, it has been shown that including psychological treatment in cardiac rehabilitation may decrease rates of mortality twofold (see Linden, Phillips, & Leclerc, 2007). The current American Heart Association treatment guidelines, released in September 2008, emphasize the importance of regular screening for, and treatment of, depression for patients with coronary heart disease (CHD), as well as closer monitoring of CHD patients receiving treatment for depression (Lichtman et al., 2008).

Given the known correlates between adverse psychosocial factors and risk of various CVD conditions (Bankier, Januzzi, & Littman, 2004), emphasis on incorporating behavioral assessment and treatment concepts into care of cardiac patients is increasingly important. The task of identifying psychosocial risk factors, however, typically falls upon medical providers (e.g., cardiologists, family medicine practitioners), who may not have specialized training in the behavioral sciences. Moreover, these providers are also overwhelmed by the need to assess and treat multiple concerns during a brief patient visit. Given the relationship between early identification and treatment of psychosocial risk factors relative to decreased mortality and morbidity rates, the growing need for an integrated approach to treating patients at risk for CVD is evident. This chapter will review the current research regarding psychosocial risk factors for CVD, as well as the current research regarding behavioral cardiology and the efficacy of behavioral interventions for prevention and treatment of cardiac disease. Specific focus on the literature regarding the

stress, hypertension, and lifestyle modification (e.g., exercise and dietary) interventions for hypertension and depression will be emphasized. In closing, recommendations regarding directions of future research to further inform and advance the practice of integrative cardiovascular medicine will be offered.

WEIGHT AND LIFESTYLE FACTORS IN THE MANAGEMENT OF CARDIAC RISK

An estimated 1 billion individuals worldwide are thought to have hypertension. In the United States, an estimated 50 million individuals suffer from elevated blood pressure levels that warrant treatment (Burt et al., 1995; Hajjar & Kotchen, 2003). Furthermore, an estimated 7.1 million deaths per year worldwide have been attributed to hypertension (World Health Organization, 2002). A report from the World Health Organization indicates that suboptimal BP (i.e., systolic BP ≥ 115 mm Hg) may be responsible for 62% of cerebrovascular disease and 49% of ischemic heart disease, with little difference between the sexes relative to prevalence rates. Moreover, elevated BP is identified as the primary attributable risk factor for death throughout the world (World Health Organization, 2002). Lifestyle factors, including tobacco use, eating habits, weight status, exercise participation, and alcohol use, are thought to be primary contributors to CVD and cardiac risk factors such as HTN. The recent INTERHEART study (Yusuf et al., 2004) reported that 90% of risk of an acute MI is predicted by the following lifestyle-related risk factors: smoking, hypertension, diabetes, central adiposity, psychosocial factors, daily consumption of fruits and vegetables, regular alcohol use, and regular physical activity, across all geographic regions of the world and for members of all ethnic groups, regardless of age or gender. Central adiposity, diabetes, and history of hypertension were second only to smoking and abnormal lipid levels relative to risk for first MI. Given these findings, which are consistent with earlier data, substantial effort has been devoted to investigating the efficacy of various biobehavioral interventions in the treatment of HTN and other CVD risk factors.

Tobacco Use

Cigarette smoking is associated with a significant increase in the risk for common CVDs, including CAD, cerebrovascular disease (Paul, Thrift, & Donnan, 2004;

U.S. Department of Health and Human Services, 1988), peripheral vascular disease, and aortic aneurysm (Burns, 2003; Hausteine, 2002), and is responsible for an estimated 140,000 premature deaths from CVDs each year (U.S. Department of Health and Human Services, 2003). Although the relationship between smoking and significant health consequences is widely known, and smoking is one of the most preventable causes of cardiovascular morbidity and mortality, the number of smokers worldwide is expected to rise from 1.3 billion in 2003 to 1.7 billion by 2025 (World Health Organization, 2003). Although a linear relationship appears to exist between amount and duration of smoking and CVD risk, it has been shown that “light” smoking (e.g., 1–4 cigarettes daily) is also associated with a threefold increase of morbidity from ischemic heart disease (Bjartveit & Tverdal, 2005; Negri, LaVecchia, Nobili, D’Avanzo, & Bechi, 1994). Despite the known consequences of smoking and the widely available treatments that are proved to be efficacious and cost effective, few providers offer smoking cessation services to their patients who smoke.

Smoking cessation interventions such as pharmacotherapy (e.g., nicotine replacement, bupropion, varenicline) and counseling-based services (e.g., cognitive-behavioral individual or group therapy, community-based programs such as quit lines) are widely available, relatively inexpensive, and effective in helping individuals achieve abstinence (Cromwell, Bartosch, Fiore, Hasselblad, & Baker, 1997). Moreover, empirical support exists to guide clinicians in the treatment of nicotine dependence (Tobacco Use and Dependence Clinical Practice Guideline Panel, Staff, and Consortium Representatives, 2000). Recent studies investigating the effect of varenicline, a relatively new selective partial agonist of the alpha-4-beta-2 nicotinic acetylcholine receptors (nAChRs) have demonstrated that this medication is more effective than placebo, and that it may also be more effective than traditional pharmacological agents (i.e., bupropion SR) in helping individuals achieve abstinence from smoking (Gonzales et al., 2006; Jorenby et al., 2006). Of importance, varenicline also demonstrated similar safety and tolerability relative to bupropion SR, suggesting that this may be a viable treatment alternative for many smokers interested in quitting.

While it is promising that new treatments demonstrating improved efficacy relative to smoking cessation are becoming available, maintaining abstinence from tobacco use may represent a more significant barrier to nicotine-dependent individuals. While more than 50% of smokers maintain abstinence for at least a few weeks (Judge, Bauld, Chesterman, & Ferguson, 2005), the majority of smokers (50%–60%) relapse within 1 year

(Ferguson, Bauld, Chesterman, & Judge, 2005; Hajek, Stead, West, & Jarvis, 2005; Marlatt & Gordon, 1985). Follow-up data of the initial varenicline trial (Tonstad, Tonnesen, Hajek, Williams, Billing, & Reeves, 2006) revealed that the majority of participants successfully maintained abstinence for 40 weeks with additional 12 weeks of treatment, indicating that this medication may be an effective agent for addressing the challenging issue of relapse. To further enhance maintenance rates, combination treatment may be the most viable alternative. Specifically, treatment that incorporates biochemical assistance with management of nicotine withdrawal, in combination with cognitive-behavioral assistance relative to motivation, behavior change, and managing cravings to smoke, may offer the greatest opportunity for success to those motivated to attempt abstinence.

The cardiovascular benefits of smoking cessation occur almost immediately (Hausteine, 2002), with research demonstrating that those with a history of acute MI who quit smoking reduce their risk of reinfarction by 25%–50% (Burns, 2003). Moreover, the reduction in all-cause mortality after quitting among individuals with established CVD is estimated at 36%, even after other risk factors are adjusted for. These mortality risk reduction benefits do not appear to apply to individuals who decrease smoking (Tverdal & Bjartveit, 2006). Given the cost-effectiveness and proved efficacy of available interventions, paired with the known health improvements associated with smoking cessation, it is critical that health care providers increase efforts to offer at least basic smoking cessation education to their patients. More research is needed to determine what the most effective intervention for smoking cessation may be for various subgroups of the population.

Weight Management

Obesity rates have risen dramatically in recent decades, particularly in industrialized nations. In fact, obesity is now identified as an “epidemic” (for discussion, see Blair & LaMonte, 2006; Campos, Saguy, Ernsberger, Oliver, & Gaesser, 2006; Flegal, 2006; Kim & Popkin, 2006; Lobstein, 2006; Orbach, 2006; Rigby, 2006; J. Stevens, McClain, & Truesdale, 2006) due to this rapid rise, which has consistently been linked with increased risk for cardiovascular disease, as well as elevated mortality rates (Flegal, Carroll, Ogden, & Johnson, 2002; National Institutes of Health, 1998). The relationship between overweight conditions and hypertension is well established (e.g., Georgiades et al., 2000; Jeffery, 1991), and the burden of this and other related CVD risk factors is expected to continue to rise as the obesity

epidemic worsens (Flegal et al., 2002). Data from the Centers for Disease Control and Prevention indicate that the U.S. obesity average, which was 12% in 1990, rose to 23% by 2005 (see Flegal, 2005, for review). In 2000, 64% of U.S. adults were identified as overweight (i.e., body mass index between 25 and 29), and 30.9% as obese (i.e., body mass index of 30 or greater). International guidelines for managing cardiovascular risk recommend weight loss as the first line of treatment (de Backer et al., 2003), although a review of epidemiological data suggests that the value of weight loss in individuals with established CVD is somewhat controversial (Anker, Negassa, Coats, Afzal, Poole-Wilson, Cohn, & Yusuf, 2003; Kennedy, Dickstein, Anker, James, Cook, Kristianson, & Willenheimer, 2006). This may primarily be a product of gaps in the literature that make it difficult to determine what specific effects weight loss may have on blood pressure. Specifically, although numerous treatment studies have examined the effect of various weight loss interventions (e.g., behavioral, pharmacotherapy, combination treatments) on blood pressure, few have investigated the effects of these treatments on hypertensive patients or compared weight loss interventions (alone) to a usual diet/lifestyle control. Instead, many studies have investigated the effectiveness of interventions that have multiple dietary and/or lifestyle components (e.g., Pérez-Stable et al., 1995), compare weight loss interventions to other treatments such as exercise (e.g., Blumenthal et al., 2000; Gordon, Scott, & Levine, 1997), include a dietary intervention for all treatment groups (e.g., Neaton et al., 1993), or allow for participants to undergo changes in antihypertensive medication use during study participation. In the Trial of Antihypertensive Interventions and Management, Langford, Davis, Blaufox, Oberman, Wassertheil-Smoller, Hawkins, and Zimbaldi (1991) examined the impact of nine psychopharmacological treatments and dietary interventions on diastolic BP (DBP), with placebo weight loss and placebo usual diet controls. However, 20% of individuals initially enrolled in the placebo usual diet condition were on either step-up or open-label psychopharmacological therapies by the end of the study. As a result, BP reductions demonstrated by the weight loss group (i.e., $-11.5/-8.8$ mm Hg) were not significantly different from BP reductions demonstrated by control participants.

Reviews of the data investigating the impact of weight loss interventions on BP suggest that weight loss interventions may produce clinically significant reductions in blood pressure in hypertensive individuals, in addition to demonstrating other clinically important changes (e.g., Mulrow et al., 2002; Staessen, Fagard, &

Amery, 1988). Furthermore, similar results have been demonstrated in normotensive individuals (e.g., V.J. Stevens et al., 1993, 2001). Regarding magnitude of BP changes produced, MacMahon, Cutter, Brittain, and Higgins (1987) reviewed results from several treatment studies and reported that a weight loss of 9.2 kg (approximately 20 pounds) was associated with a reduction of 6.3 mm Hg systolic blood pressure (SBP) and 3.1 mm Hg DBP. In a recent meta-analysis, Neter, Stam, Kok, Grobbee, and Geleijnse, (2003) reported that a weight loss of 5.1 kg (approximately 11 pounds) reduced SBP by 4.44 mm Hg, with a DBP reduction of 3.57 mm Hg. Avenell and colleagues (2004) also conducted a meta-analysis reviewing randomized controlled trials (RCTs) investigating the longer-term impact of weight loss on BP (i.e., studies with follow-up assessments of at least 1 year after treatment), and findings revealed that a 10% weight loss was associated with decrease in SBP of 6.1 mm Hg. Recent interventional trials have also demonstrated meaningful reductions of SBP (7–10 mm Hg) and DBP (6–7 mm Hg) following a weight loss of roughly 8 kg (Blumenthal et al., 2000; Dengel, Galecki, Hagberg, & Pratley, 1998). In summary, these data have consistently supported the existence of a strong relationship between weight and BP and, moreover, the efficacy of weight loss interventions in reducing BP in overweight individuals who are normotensive or hypertensive (see Blumenthal, Sherwood, Gullette, Georgiades, & Tweedy, 2002).

Dietary Components

Dietary and lifestyle modification is widely accepted as an important contributor to BP changes over time. Thus, various HTN interventions target specific dietary factors, including reduction of alcohol use and sodium intake and supplementation of various nutrients (e.g., potassium, magnesium, and calcium) that have been shown to produce reductions in BP (e.g., Cutler, Follmann, & Allender, 1997; Whelton, He, Cutler, Brancati, Appel, Follmann, & Klag, 1997). A recent review of dietary interventions in the treatment of HTN (i.e., studies of sodium restriction; alcohol restriction; and potassium, magnesium, and calcium supplementation) concluded that a balanced approach to eating was the optimal dietary approach to BP reduction (Blumenthal et al., 2002).

Alcohol

Epidemiological data have consistently shown alcohol consumption to be associated with elevations in BP (e.g., Beilin, Puddey, & Burke, 1996). However, some confusion exists regarding the issue of a threshold

effect relative to the impact of alcohol consumption on BP. While many reports suggest that a linear relationship between alcohol consumption and BP exists, a review of 30 cross-sectional studies (MacMahon et al., 1987) revealed that in 40% of studies reviewed, non-drinkers demonstrated higher BP than those who consumed 1–2 alcoholic beverages per day. Findings from the Atherosclerosis Risk in Communities Study (Fuchs, Chambless, Whelton, Nieto, & Heiss, 2001) suggest that the mixed findings relative to the relationship between alcohol use and BP may be associated with group differences in responding. Specifically, the researchers reported that while consuming 210 or more grams of alcohol per week was found to be an independent risk factor for HTN, consumption of low to moderate amounts of alcohol was only associated with HTN for black males in the study. Overall, while larger amounts of alcohol consumption have shown a dose-related effect on BP in hypertensive and normotensive individuals, modest alcohol consumption has, generally, not been associated with increases in BP (Whelton et al., 2002). Because both cross-sectional and observational studies (e.g., Gordon & Doyle, 1986; Gordon & Kannel, 1983; Kromhout, Bosschieter, & Coulander, 1985) have demonstrated a direct relationship between alcohol consumption and BP, the Joint National Committee (2003) report suggests limiting daily alcohol intake to a modest level (i.e., <30 grams, or 2 drinks) daily.

Interestingly, few studies have investigated the relationship between alcohol use and BP in individuals who consume light to modest amounts of alcohol. Rather, the majority of literature has emphasized alcohol restriction and BP in alcohol-dependent individuals during and after a period of detoxification (e.g., Aguilera, de la Sierra, Coca, Estruch, Fernandez-Sola, & Urbano-Marquez, 1999; Saunders, Beevers, & Paton, 1981). Nonetheless, the overall findings suggest that reducing alcohol intake may produce reductions in BP, particularly in those who consume large amounts of alcohol on a regular basis. In Keil, Liese, Filipiak, Swales, and Grobbee's (1998) review of the literature, it was found that chronic (daily) intake of 30–60 grams (or more) of alcohol results in elevations in BP, and that reducing alcohol consumption is an effective method of lowering BP. Interestingly, Cushman and colleagues (1998) conducted a RCT of moderate alcohol restriction on BP and found that decreasing consumption by 1.3 drinks per day did not produce significant BP reductions. However, baseline alcohol consumption for participants enrolled in the study was not classified as "heavy" (440 g/week; Bulpitt & Shipley, 1999), which may explain this finding. Based on findings of the available research, includ-

ing the demonstrated benefits of moderate alcohol use on CAD risk (Joint National Committee, 2003), an overall recommendation of moderate alcohol consumption for most individuals may be warranted.

Sodium

The existence of a relationship between dietary sodium intake and the development of HTN is widely accepted and is well supported by research demonstrating higher BP levels in cultures that chronically consume higher levels of dietary sodium (e.g., Midgley, Matthew, Greenwood, & Logan, 1996). However, intracultural studies have shown more mixed results. Specifically, while results from the Scottish Heart Health Study (Smith, Crombie, Tavendale, Gulland, & Tunstall-Pedoe, 1988) did not support a relationship between sodium and BP, the International Study of Salt and Blood Pressure (Stamler, 1997) found that a significant linear relationship between sodium and SBP existed. More recent reviews of epidemiological data and RCTs of sodium restriction and BP have reported similarly mixed results (e.g., Cutler et al., 1997; Graudal, Galloe, & Garred, 1998). To add complexity to this issue, individual differences have been documented relative to BP response to sodium (Joint National Committee, 2003), with some individuals (e.g., African Americans) demonstrating a sensitivity to salt that results in a rise in BP after high sodium intake. For more salt-resistant individuals, this rise in BP is not demonstrated. Moreover, data exist that suggest severe restriction of sodium intake may produce detrimental effects on health, such as suboptimal changes in lipid levels (e.g., Egan, Weder, Petrin, & Hoffman, 1991). Severe sodium restriction has also been linked with increased rates of cardiovascular morbidity and mortality (e.g., Alderman, Madhavan, Cohen, Sealey, & Laragh, 1995). In general, data support a recommendation for hypertensive sodium-sensitive individuals, who typically consume high amounts of dietary sodium, to decrease sodium intake for the purpose of reducing BP. However, this recommendation is not well supported for normotensive individuals or for salt-resistant individuals. More research is needed to clarify the relationship between sodium intake and BP in various populations, as well as to clarify the impact of longer-term sodium restriction on rates of cardiovascular morbidity and mortality.

Dietary Supplementation

Early studies of environmental contributors to BP changes support a relationship between hard water and

HTN. As a result, researchers began investigating the role that dietary mineral supplementation (e.g., potassium, magnesium, and calcium) may play in BP changes. Of the identified contributors to BP changes, potassium has been shown to produce the most significant impact relative to BP reduction and the prevention of HTN. Potassium intake has been found to demonstrate an inverse relationship to BP in epidemiological studies (e.g., Rodriguez, Labarthe, Huang, & Lopez-Gomez, 1994). As a result, various studies have investigated the impact of increased potassium intake on BP and have demonstrated mixed findings (e.g., Brancati, Appel, Seidler, & Whelton, 1996; Grimm et al., 1996). In a meta-analysis of 33 RCTs in which potassium supplementation was the only difference between intervention and control conditions, Whelton and colleagues (1997) reported that potassium supplementation produced significant reductions in SBP (-3 mm Hg) and DBP (2 mm Hg). Furthermore, they reported that greater potassium-related reductions in BP were associated with higher sodium intake, thus emphasizing the importance of the dietary balance relative to sodium and potassium intake. This balance may be particularly important for those who tend to demonstrate higher levels of salt sensitivity, such as African Americans. For example, in an examination of three dietary interventions (low salt, high salt, and high potassium with high salt) in a primarily African American sample, West, Light, Hinderliter, Stanwyck, Bragdon, and Brownley (1999) produced similar reductions in BP for salt-sensitive participants in the low salt and increased potassium conditions. Interestingly, no changes in BP across diets in were seen in salt-resistant individuals. In general, increased potassium intake appears to have a weak positive effect on BP, which may be stronger in salt-sensitive individuals. Further research is needed to clarify whether adequate BP changes may be achieved through dietary potassium supplementation.

Regarding calcium supplementation, recent meta-analytic data demonstrated an association between dietary calcium intake and DBP (Cappuccio, Elliott, Allender, Pryer, Follman, & Cutler, 1995). In Cappuccio et al.'s review, 23 population studies were evaluated, and results indicate that an inverse relationship between calcium intake and BP exists. In a second study, this group performed a meta-analysis of 22 RCTs of the effects of calcium supplementation on BP and found that supplementation resulted in minor reductions in SBP (1 mm Hg) and DBP (0.2 mm Hg). Larger decreases in SBP were demonstrated by hypertensives than by normotensive counterparts. Given the insignificant effects demonstrated across the data, it seems unlikely

that recommendations regarding calcium supplementation alone are warranted in the treatment of hypertension at this time.

Research studies that have investigated the relationship between magnesium supplementation and BP are fewer and often include small sample sizes. However, the extant literature suggests that magnesium supplementation may have a positive effect on BP (e.g., Dyckner & Wester, 1983; Motoyama, Sano, & Fukuzaki, 1989; Widman, Wester, Stegmayr, & Wirell, 1993). More rigorous trials of magnesium supplementation on BP have demonstrated mixed results (Kawano, Matsuoka, Takishita, & Omae, 1998; Yamamoto et al., 1995); thus more research is needed to determine whether magnesium supplementation alone is beneficial for BP reduction.

Combination Dietary Interventions

A number of studies have examined the efficacy of combining a series of dietary nutrient supplementation in treating hypertension. For example, the DASH (Dietary Approaches to Stop Hypertension) study, a multicenter, randomized feeding trial, was designed to evaluate the impact of three specific dietary patterns on BP among individuals with elevated DBP, or identified as stage 1 hypertensive, who were unmedicated (Appel et al., 1997; Conlin et al., 2000; Windhauser et al., 1999). Over the course of an 8-week treatment program, participants were provided with all meals/snacks, which were specific to their individual nutritional needs (e.g., appropriate calorie levels), as determined by staff dietitians. Treatment groups received a control diet representative of the average American diet, a diet high in fruits and vegetables but otherwise similar to the control diet, and a combination diet (i.e., the DASH diet) emphasizing fruit, vegetable, and low-fat dairy intake. The DASH diet was low in sodium, total fat, saturated fat, and cholesterol, and rich in minerals identified as important in BP reduction (i.e., magnesium, calcium, potassium). Sodium content and body weight were kept constant through the entire study. Participants receiving the DASH diet demonstrated reductions in SBP (-5.5 mm Hg) and DBP (3.0 mm Hg), and those individuals identified as hypertensive demonstrated the largest reductions in BP ($-11.4/-5.5\text{ mm Hg}$). Normotensive participants also demonstrated reductions in BP, although they were more modest ($-3.5/-2.1\text{ mm Hg}$; Appel et al., 1997). Of additional importance, African Americans in the Appel et al. (1997) DASH study demonstrated the greatest improvements in BP with the DASH diet.

In a follow-up DASH diet study, Sacks and colleagues (2001) compared the impact of varying levels of sodium intake and two dietary programs on BP in unmedicated stage 1 hypertensives. Participants were randomly assigned to either a DASH diet or a control condition similar to that in the prior study, and a cross-over design allowed for participants to receive three different sodium levels (150, 100, 50 mmol/d for a 2,100 kcal diet) for a total of 30 days on each dietary plan. Those receiving the DASH diet demonstrated superior reductions in SBP across all sodium levels and, not surprisingly, reductions in sodium intake were associated with more significant decreases in SBP for both dietary conditions. In general, it appears that the DASH diet is effective in reducing BP and may be particularly effective in reducing BP in African Americans, who suffer the highest rates of HTN and related complications (Svetkey et al., 1999). A limiting factor of these studies is that both were feeding studies that provided all participants with prepared food that was adjusted for individual calorie needs. Although this design element may limit generalization of findings, the results hold significant importance in the hypertension treatment and prevention literature. In fact, based on findings from these important studies, the DASH diet is now recommended for the treatment and prevention of HTN (Joint National Committee, 2003).

Combination Dietary and Weight Loss Interventions

Recent studies have explored the impact of dietary changes in combination with weight loss interventions on BP. For example, the TONE study (Whelton et al., 1998) was an RCT designed to evaluate the impact of single-component dietary and weight loss interventions, combined low-sodium and weight loss treatment, and usual care on BP. Of the total 975 participants, all of whom were treated with one antihypertensive medication, 585 were identified as obese and were randomized to one of four conditions (i.e., low-sodium diet, weight loss, low-sodium diet plus weight loss, or usual care). Obese participants receiving the combined intervention demonstrated the largest reductions in BP ($-5.3/-3.4$ mm Hg). Smaller reductions were demonstrated for the weight loss ($-4.0/-1.1$ mm Hg) and low-sodium ($-3.4/-1.9$ mm Hg) groups. Of potentially greater importance, compared to the usual care condition, there appeared to be a decrease in risk for morbidity and mortality associated with all three alternative conditions, according to hazard ratio data evaluated

in the study (0.60 for low sodium alone, 0.64 for weight loss alone, 0.47 for combined weight loss and low sodium). These findings suggest that dietary changes, particularly when weight loss is emphasized, may have significant benefits in the treatment of hypertension, particularly in obese individuals.

In 2002, Miller and colleagues conducted the first RCT (DEW-IT; Diet, Exercise, and Weight Loss Intervention Trial) aimed at evaluating the efficacy of a multidimensional treatment on BP. Forty-four overweight participants identified as pre-hypertensive or hypertensive, who were taking only one antihypertensive medication, were assigned to either a 9-week comprehensive lifestyle intervention including DASH-diet (food provided) plus 3 supervised aerobic exercise sessions per week or a no-treatment control. Neither group was encouraged to lose weight. The lifestyle intervention group demonstrated reductions in 24-hour ambulatory BP of -9.5 mm Hg (DBP) and -5.3 mm Hg (SBP). Although the small sample size in this study limits the generalizability of findings, results support the notion that individuals treated with pharmacotherapy for HTN may further reduce BP through participation in a structured dietary and exercise program. In 2003, the PREMIER study (PREMIER Collaborative Research Group, 2003) evaluated the combined effects of pairing the DASH diet with a multicomponent lifestyle intervention for BP in unmedicated pre-hypertensive or hypertensive individuals. This study was an 18-month multicenter trial consisting of a total of 810 participants assigned to one of three groups: (1) advice only, a 30-minute educational session on how to reduce BP; (2) “established intervention,” a 6-month behavioral intervention for weight loss, involving sodium reduction, increased physical activity, and limited alcohol intake; or (3) established intervention plus instruction in DASH diet practices. Following treatment, all groups demonstrated reductions in SBP, although the two groups receiving the behavioral interventions demonstrated the most significant reductions (i.e., -6.6 mm Hg advice only; -10.5 mm Hg established intervention; 11.1 mm Hg established + DASH). Of importance, the PREMIER study did not evaluate the effect of DASH diet alone on BP and also did not control for weight loss; thus, it is difficult to understand the comparative impact of behavioral intervention components on outcome. More recent trials are examining the independent contributions of behavioral interventions. For example, Blumenthal and colleagues at Duke University Medical Center in 2009 completed data collection for the ENCORE study, which was designed to evaluate the independent contributions of DASH diet alone and DASH in combination

with a behavioral weight loss program (i.e., CBT, nutrition, and exercise components), relative to a usual care condition in healthy individuals identified as overweight, pre-HTN, or HTN. Treatment incorporated weekly meetings with either a dietician (DASH only) or a dietician, psychologist, and exercise physiologist (combination treatment), and treatment was delivered in a “free-living” environment over a 4-month period. Results from this study promise to address some of the remaining questions regarding the relative impact of independent components of multidimensional behavioral treatments for HTN.

THE RELATIONSHIP BETWEEN PSYCHOSOCIAL STRESS AND HEALTH

CVD is the leading cause of mortality and disability in the United States (Murray & Lopez, 1996; World Health Organization, 2003), and a vast body of literature links CVD to stress (see Dimsdale, 2008; Hamer, Taylor, & Steptoe, 2006). In the INTERHEART study (Yusuf et al., 2004), a case-control study of acute MI in 52 countries relative to a variety of known, potentially modifiable correlates of heart disease (e.g., diabetes, waist/hip ratio, dietary patterns, activity levels, alcohol and tobacco use, psychosocial factors), demonstrated that 90% of risk of an acute MI was predicted by the risk factors assessed in the study (i.e., smoking, hypertension, diabetes, central adiposity, psychosocial factors, daily consumption of fruits and vegetables, regular alcohol use, and regular physical activity). This relationship, importantly, was consistent across all geographic regions of the world and for individuals of all ethnic groups, regardless of age or gender. Psychosocial variables, as well as central adiposity, diabetes, and history of hypertension, were second only to smoking and abnormal lipid levels in relation to occurrence of an individual's first MI. The authors concluded, therefore, that prevention efforts regarding CVD may be based on a similar set of principles worldwide, which, if applied effectively, could assist in the prevention of early acute MI.

Regarding the psychosocial and psychological risk factors of CVD, it has been shown that individuals who demonstrate an exaggerated response to life stressors (e.g., coronary-prone or type-A behavior patterns) may be at increased risk of developing heart disease and/or associated risk factors (e.g., hypertension). In addition to traditional treatments for CVD risk factors such as hypertension (i.e., antihypertensive pharmacotherapies), exercise training has been shown to reduce coronary-prone behaviors such as hostility and anger

and may also lower cardiovascular reactivity to psychosocial stress. Exercise may also aid in reducing resting BP, as well as BP in response to laboratory stress-induction procedures, in hypertensive individuals. Exercise may reduce hemodynamic reactivity to a level targeted by antihypertensive pharmacotherapies, and effect may be most evident when paired with a behavioral weight loss program (Georgiades et al., 2000). These findings suggest that exercise participation may be important to the management of cardiovascular response (e.g., blood pressure) to psychosocial stress and support the importance of including exercise as an adjunct treatment in the long-term management of CVD. This relationship between exercise training, stress reactivity, and CVD risk has been the focus of a number of research investigations in recent years.

In addition to increasing risk for CVD, stress has been linked with various psychiatric disorders. Research has consistently supported the role of elevated life stress, as well as exaggerated reactivity to stress, in mood episode onset/relapse relative to various psychological disorders, particularly in more chronic and severe forms of illness (Basco & Rush, 1995, 1996; Gitlin, Swendsen, Heller, & Hammen, 1995; Miklowitz, 2001; Miklowitz & Goldstein, 1997). It is widely accepted that individuals with various forms of psychiatric illness (e.g., bipolar disorder) experience an increased number of stressful events prior to episode onset, as well as a disruption of daily routine (i.e., social rhythms), which place the individual at increased risk for episode relapse (Miklowitz & Goldstein, 1997). Current research supports this stress-attenuation benefits of exercise participation for individuals ranging in psychiatric symptom severity (i.e., subclinical to clinical populations). Further research is needed to address questions relative to the degree to which duration, intensity, and modality of exercise may affect health outcomes associated with exercise (e.g., mood enhancement, stress reduction, obesity management), so that “prescription” guidelines that may produce optimal benefits for various subpopulations may be formulated (see Barbour, Edenfield, & Blumenthal, 2007; Edenfield & Blumenthal, in press).

Stress Management Therapies

Numerous studies investigating the efficacy of various stress management interventions have been conducted over the past three decades. These treatment approaches typically attempt to assist individuals in learning cognitive strategies that help them think about life situations and their personal responses in a more balance and helpful manner. In addition, behavioral

strategies (e.g., relaxation training) aimed at reducing reactivity to stressful events are a common component of stress management therapy. The effectiveness of the most common interventions has been evaluated by several meta-analytic studies (e.g., Eisenberg, Delbanco, Berkey, Kaptschuk, Kupelnick, Kuhl, & Chalmers, 1993; Jacob, Chesney, Williams, Ding, & Shapiro, 1991; Linden & Chambers, 1994). A review of the application of biobehavioral approaches to the treatment of hypertension, including stress management therapies, was conducted by Blumenthal and colleagues (2002). The most common forms of stress management therapies—biofeedback training, behavioral relaxation techniques and cognitive-behavioral therapy—are reviewed here.

Biofeedback

Biofeedback is a treatment technique designed to learn how an individual responds to various events (e.g., headache, pain), and to teach patients how to improve their ability to self-regulate somatic processes for the treatment of various health conditions (e.g., chronic pain, insomnia, neurological disorders, and hypertension). A variety of biofeedback techniques exist, including thermal, electroencephalographic, galvanic skin response, electromyographic (EMG), and BP feedback. Thermal biofeedback involves attaching sensors to fingers or feet to measure skin temperature to help an individual learn when to implement relaxation techniques. Skin temperature in these regions tends to drop when an individual is under stress. Given the relationship between stress and elevated muscle tension and pain experiences, this technique is commonly used to treat certain pain conditions (e.g., Raynaud's syndrome) that typically involve noticeable changes in circulation (e.g., skin color and temperature). Electroencephalographic biofeedback involves measurement of brain activity (e.g., sleep-wake cycles) by sensors connected to appropriate regions of the cranium and is typically used in the assessment and treatment of sleep (e.g., insomnia) and neurological disorders (e.g., epilepsy). In galvanic skin response training, electrodes measure sweat response, which is highly correlated to stress, or anxious styles of responding. This type of biofeedback training is useful for treating anxiety disorders.

EMG biofeedback is the most commonly used technique, as it is easy to use, reliable, and less invasive than the application of recording electrodes. EMG techniques are typically used in adjunct with behavioral relaxation training (e.g., progressive muscle relaxation) so that individuals may learn the benefits of self-regulation of muscle tension/relaxation, and the

impact that relaxation and self-regulation have on physiological processes. BP biofeedback is a more difficult technique to master and is used less commonly. Forms of BP biofeedback have been criticized for various reasons, with standard sphygmomanometry often perceived as cumbersome, automated devices as slow and distracting to participants, and direct BP measurement using arterial catheterization as invasive and impractical. Shapiro, Tursky, Gershon, and Stern (1969) developed a noninvasive BP feedback procedure that uses a constant cuff technique in which BP is measured with each heartbeat. A microphone is placed near the participant's elbow to detect Korotkoff sounds (K-sounds), and an EKG record permits detection of a K-sound with each heartbeat. To train patients to self-regulate (i.e., lower) BP, the cuff is inflated so that the K-sounds are detected half of the time. Patients are reinforced during trials for heartbeats that are not followed by a K-sound, and a process of shaping (e.g., deflating the cuff by 2 mm Hg and repeating the process) is introduced until a new median SBP is reached. Although Shapiro and colleagues demonstrated that it is possible for individuals to learn to lower BP with this technique, the method is not easily adapted for clinical practice and therefore is seldom used.

Some researchers, such as Agras and Jacob (1979), have suggested that pairing relaxation training with biofeedback does not offer added benefit to the treatment of hypertension. Biofeedback as a singular treatment has shown limited effectiveness in reducing BP (Jacob et al., 1991; Eisenberg et al., 1993). For the studies that have shown biofeedback to have an effect on BP, difference produced were generally not significantly greater than BP reductions demonstrated by placebo or sham biofeedback interventions (e.g., Blanchard, Eisele, Vollmer, Payne, Gordon, Cornish, & Gilmore, 1996; Henderson, Hart, Lal, & Hunyor, 1998; Hunyor et al., 1997).

Behavioral Relaxation Techniques

Relaxation techniques, including progressive muscle relaxation, meditation, and yoga, have been utilized as interventions in the treatment of HTN. In the Hypertension Intervention Pooling Project, Kaufmann, Jacob, Ewart, Chesney, Muenz, Doub, and Mercer (1988) reviewed 12 randomized controlled trials of relaxation therapies in the treatment of HTN. The studies reviewed examined the use of relaxation therapy alone, relaxation combined with biofeedback, and relaxation in combination with other treatments (e.g., dietary counseling or cognitive therapy techniques) in participants who were either medicated or unmedicated for HTN. Findings from this

meta-analysis revealed a modest yet statistically significant decrease in DBP in unmedicated participants. No significant improvements in DBP recordings were demonstrated in pharmacologically managed individuals, and no significant effect on SBP was found in any group of participants (medicated or unmedicated). The investigators also noted that participants with higher pretreatment BP levels showed the greatest change, which may be the result of a floor effect, which would make it difficult to observe significant improvements in BP in a sample of individuals not suffering from more severe levels of hypertension. Other meta-analyses have suggested that relaxation therapy, relative to combination treatments, may have no significant impact on BP levels (e.g., Jacob et al., 1991).

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) techniques in the form of core strategies that assist individuals in altering the way stressful events are perceived and responded to have been shown to be effective in the reduction of excessive stress reactivity. The approach includes techniques such as cognitive restructuring, adaptive emotional learning and coping strategies, imagery and visualization, and relaxation training. Some researchers have consistently demonstrated significant reductions in BP, and associated decreases in individuals' need for HTN medication, through a combination of meditation, diaphragmatic breathing techniques, behavioral stress management, and biofeedback (e.g., Patel, 1991). As early as 1975, Patel and North (1975) reported significant reductions in BP in hypertensives receiving CBT for stress management relative to controls. Other studies, however, have not replicated these findings. In phase 1 of the Trials of the Hypertension Prevention (TOHP-I) project, Batey and colleagues (2000) investigated CBT stress management as one of seven nonpharmacologic approaches aimed at lowering DBP in healthy men and women ages 30–54, with DBP baseline measurements ranging between 80 and 89 mm Hg. The investigators reported that the only significant effect was a 1.36-mm Hg reduction in DBP relative to controls at the end of the trial for stress management participants who attended 61% or more of the intervention sessions. The authors concluded that stress management was an unlikely candidate for a primary prevention technique for HTN in a general population.

Single-Component Versus Multi-Modal Therapies

After single-treatment trials revealed limited efficacy relative to BP reduction, researchers began to investigate

combination therapy approaches. In Jacob and colleagues' (1991) meta-analysis, which evaluated 75 treatment groups and 41 control groups, single-component therapies (e.g., relaxation or meditation) showed small effects, or no reductions, in BP (i.e., -5.7 to $+3.5$ mm Hg for SBP; -3.1 to $+2.3$ mm Hg for DBP). In a subsequent meta-analysis, Eisenberg and colleagues (1993) evaluated more than 80 treatment studies that investigated the efficacy of CBT for HTN. However, only 26 of the considered studies met criteria for RCTs with sufficient data to be included in the meta-analysis. These researchers concluded that single-component interventions resulted in no significant effect on SBP or DPB but also noted that combination therapy did show more promising results, with reductions in SBP of -13.5 mm Hg and DBP of -3.4 mm Hg. Linden and Chambers (1994) conducted a meta-analysis comparing 90 RCTs investigating stress reduction as a treatment for HTN, 30 of which used pharmacological interventions (i.e., diuretics, beta-blockers, or calcium channel blockers versus placebo), and 47 of which used behavioral interventions (i.e., weight loss, exercise, sodium restriction, alcohol restriction, calcium supplementation, or potassium supplementation). Similar to previous evaluations, single-component therapies resulted in small to no reductions in BP. However, multicomponent stress management interventions were found to reduce BP more significantly (i.e., $-9.7/-7.2$ mm Hg), and for a longer duration. Individualized cognitive therapy for stress management resulted in the greatest reductions in BP, with an average decrease in SBP of -15.2 and in DPB of -9.2 mm Hg. In this study, stress management, exercise, and pharmacological interventions were shown to be equally successful in reducing SBP, whereas pharmacotherapy was the most effective in reducing DBP.

Early studies investigating the effects of various nonpharmacological interventions in the treatment of HTN, including biofeedback, relaxation techniques and cognitive-behavioral therapy, suffered significant methodological limitations, including small sample sizes, inadequate control comparisons, and unstable baseline BP measurements. More rigorous investigations, including RCTs of single-component therapies (e.g., relaxation or biofeedback training), have demonstrated only small BP reductions. Moreover, the results that have been demonstrated have often not been significantly greater than those shown in response to placebo or sham biofeedback interventions. Thus, given the limited and inconsistent findings to date, stress management therapy cannot be recommended as a sole primary intervention technique for HTN. More recent studies have, however, shown some promise for multicomponent therapies

(i.e., CBT for stress management) relative to BP reduction. This may be representative of the aforementioned relationship between elevated stress levels, or elevated stress reactivity (e.g., in coronary prone or type A individuals) and HTN, and may offer additional support for the potential benefits of stress management and relaxation therapies in these populations. Such therapies may offer a valuable adjunctive method of BP management, resulting in quality-of-life improvements and a reduction of cardiovascular risk. More research is needed to further evaluate the effectiveness of multicomponent stress management therapies on HTN.

EXERCISE AND PSYCHOSOCIAL STRESS

The overall benefits of exercise are widely accepted, and substantial epidemiological data support a positive relationship between exercise, physical health, and overall quality of life (e.g., Lee, Hsieh, & Paffenbarger, 1995; Leon, Connett, Jacobs, & Rauramaa, 1987; Paffenbarger, Hyde, Wing, Lee, Jung, & Kampert, 1993; Paffenbarger, Hyde, Wing, & Steinmetz, 1984; Warburton, Nicol, & Bredin, 2006). Exercise has consistently demonstrated an ability to contribute to the prevention of various medical conditions such as hypertension, diabetes, CVD, cancer, and osteoporosis (e.g., Fentem, 1994; Warburton et al., 2006). Moreover, participation in a regular program of exercise has been shown to reduce the incidence of premature mortality (e.g., Paffenbarger & Hyde, 1988; Paffenbarger et al., 1993). As a result of these findings, researchers in various professions (e.g., physicians, exercise physiologists, nurses, clinical and health psychologists) have begun to focus their attention on investigations of the relationship between exercise initiation/maintenance and outcomes relative to health and functioning.

Exercise is known to produce various physical health benefits, and research in recent decades has also documented various psychological benefits (Camacho, Roberts, Lazarus, Kaplan, & Cohen, 1991; Lawlor & Hopker, 2001; Martinsen, 1995; McAuley, 1995; Mutrie & Biddle, 1995; Scully, Kremer, Meade, Graham, & Dudgeon, 1998). There have been anecdotal reports regarding the positive effects of exercise (e.g., the so-called feel-good effect or runner's high) for centuries, with claims rooted in philosophical ideas originating more than 2,500 years ago. At that time, Socrates and Plato argued that physical activity and training were essential in man's search for virtue. Hippocrates and Galen, likewise, argued that excessive levels of exercise participation or restriction were detrimental to overall health

(e.g., Berryman, 1989; Eaton & Shostak, 1988; Galen, trans. 1951). Currently, there is growing evidence to support the philosophical claims that exercise offers a beneficial effect relative to psychological and emotional well-being (see Salmon, 2001; Scully et al., 1998). In fact, researchers have begun to investigate whether a dose-response relationship between exercise participation and positive health changes exists, as well as the role of changes in physical fitness relative to benefits to psychological well-being and stress reactivity (e.g., Dunn, Trivedi, Kampert, Clark, & Chambliss, 2002, 2005; Hamer, Stamatakis, & Steptoe, 2008; Hamer et al., 2006; Lawlor & Hopker, 2001).

Defining Exercise

Exercise can be defined as participation in a program of regular, structured physical exertion of varying degrees of intensity and duration designed to elevate heart rate and/or increase muscle strength. Physical activity, a related concept, involves physical exertion absent of the intent to elevate heart rate and may involve various unstructured activities such as occupational and domestic tasks. Exercise may be broken into two groups: aerobic (literally "with oxygen") and anaerobic ("without oxygen") activities. Aerobic exercise involves sustained activity for which the body requires larger amounts of oxygen to perform (e.g., jogging, walking, and cycling). Oxygen is used by muscles to burn fat and glucose in order to produce adenosine triphosphate, which supplies energy to the body's cells. Conversely, during anaerobic exercise, the muscles depend upon the metabolism of muscle glycogen to produce power instead of relying upon large amounts of oxygen. In short, anaerobic exercise involves short bouts of high-intensity exertion (e.g., weight lifting, sprinting, jumping) for which the body does not rely upon oxygen as its source of energy.

Although participation in aerobic exercise is widely accepted as a necessary contributor to optimal cardiovascular health, there is evidence that both aerobic and anaerobic exercises (strength training) can improve psychological health. Aerobic exercise has been more widely studied relative to anaerobic training, but including both forms of exercise is essential to achieving optimal health benefits. In 1995, both the American Society of Sport Medicine and the Centers for Disease Control and Prevention recommended that adults engage in at least 30 minutes of moderate physical activity most days of the week to improve overall health and well-being (Pate et al., 1995). A statement on health and physical activity from the U.S. Surgeon General's Office in 1996 indicates that inclusion of regular physical

activity is essential for maintaining physical and psychological well-being (U.S. Department of Health and Human Services, 1996). In addition, the *Healthy People, 2010* objectives (U.S. Department of Health and Human Services, 2000) include increasing the proportion of adults who regularly engage in moderate-intensity or vigorous exercise to 50% or more. Sedentary lifestyle has been consistently linked with an increase in risk of all-cause mortality (Paffenbarger & Hyde, 1988), while adoption and/or maintenance of regular exercise is widely known to reduce the risk of mortality (Hakim et al., 1998; Leon & Connett, 1991; Leon, Myers, & Connett, 1997; Paffenbarger, Kampert, Lee, Hyde, Leung, & Wing, 1994; Yusuf et al., 2004). Exercise has consistently been shown to result in an inverse dose-response relationship with various medical illnesses (e.g., coronary heart disease; Blair, Goodyear, Gibbons, & Cooper, 1984; Martin, Dubbert, & Cushman, 1990; Yusuf et al., 2004), and is thought to have potential for preventing or decreasing an individual's risk for other illnesses such as colon cancer, diabetes mellitus (e.g., Helmrigh, Ragland, Leung, & Paffenbarger, 1991), and osteoporosis (see Dubbert, 1992; Warburton et al., 2006).

The cardiovascular benefits of exercise are well established and have guided researchers in their efforts to investigate the potential psychological benefits of exercise. For example, the duration of an exercise training program typically used in psychological research is 8–12 weeks, a period of training that has been proved necessary to produce cardiopulmonary conditioning effects (i.e., improved physical fitness). Similarly, when measuring fitness, or the body's capacity for aerobic work (i.e., oxygen uptake measured by maximal exertion VO_2 max, assessments), researchers have emphasized the importance of aerobic exercise training. Alternative programs of exercise training have been developed in research (e.g., non-strenuous flexibility and relaxation programs), but these interventions are most often used as control conditions in studies of aerobic exercise training because they do not produce significant changes in cardiovascular functioning (Desharnais, Jobin, Cote, Levesque, & Godin, 1993; Heaps, 1978; Hilyer & Mitchel, 1979; Ransford & Palisi, 1996).

Although exercise is widely accepted as an essential component of a healthy lifestyle, and the importance of including a healthy regimen of physical activity across the life span has been emphasized in recent consensus statements, few people achieve the recommended guidelines regarding exercise participation (i.e., at least 30 minutes of moderate physical activity most days; American Society of Sport Medicine and the Centers for Disease Control and Prevention, cited in Pate et al., 1995;

U.S. Department of Health and Human Services, 1996). Approximately 60% of adults in the United States are mostly sedentary, and 22% of adults report engaging in no leisure-time activity (Centers for Disease Control and Prevention, 1996). The Centers for Disease Control and Prevention (2005) reported similar findings, identifying 25% of the U.S. population as mostly sedentary, and thus failing to achieve recommended levels of physical activity. Brawley and Rodgers (1993) reported that only about 30% of individuals in Western societies engage in significant levels of exercise. Moreover, they reported that even when a program of exercise is initiated, approximately 50% of exercisers become sedentary within 3–6 months. Individuals in specialized sectors of the population (e.g., those suffering from psychiatric illnesses) are thought to be even more sedentary than individuals from the general population (Goldberg & Huxley, 1992; Martinsen, Hoffart, & Solberg, 1989). Findings supporting this difference in activity level relative to psychological health status have long raised the question of causality: do individuals exercise less because they suffer from mental illness, or does a lack of exercise cause mental illness?

Defining Stress

The concept of stress is most commonly defined as a stimulus (e.g., an acute, time-limited, or chronic event that results in a stress response). Examples, according to this definition, include events such as a natural disaster, death of a spouse, or a laboratory challenge (e.g., mental arithmetic, cold pressor task), an emotional or physical response (e.g., anxiety or a physical response such as heart rate or blood pressure changes; Selye, 1974), or an interaction between an individual and his or her environment (e.g., someone suffers a heart attack while watching an intense football game; Lazarus & Folkman, 1984). In the current literature, stress is commonly viewed as a complex interaction between mental state, emotional experiences, and physiological and biochemical adaptations (e.g., Cohen, 2000; Cooper, 1996; Hubbard & Workman, 1998). Although negative life events (e.g., loss, financial strain) are often highlighted when individuals describe stressors, likely because they are considered to pose greater threat to an individual, stressors may also include more positive challenges. New challenges that may not be identified as primarily negative in nature, such as a job promotion or having a child, may trigger the stress response in the same way a negative stressor (e.g., losing a job) would and may demand similar levels of energy and attention.

Stress has been linked to various health consequences and is also a common patient complaint across medical settings (Dimsdale, 2008; Hamer et al., 2006; Manuck, 1994; Manuck, Kamarck, Kasprowicz, & Waldstein, 1993). Health consequences that have been associated with stress include coronary heart disease (CHD) and essential hypertension (Carroll, 1992; Eliot, Buell, & Dembroski, 1982; Frank & Smith, 1990; Goldstein & Niaura, 1992; Manuck, 1994; Niaura & Goldstein, 1992; Pickering, 1991; Treiber, Karamak, Schneiderman, Sheffield, Kapuku, & Taylor, 2003). Measures of stress response range from self-report questionnaires asking individuals to report on the nature, severity, and chronicity of stressors experienced to physiological and behavioral measures of reactivity, which may manifest itself in terms of heart rate, blood pressure, respiratory rate, and/or neuroendocrine responses (see Cohen, 2000; Krantz & Manuck, 1984; Kuhn, 1989; Manuck et al., 1993) and are often the target of laboratory assessment of the stress response.

Physiological Assessment of the Stress Response

There is an underlying assumption that studying physiological reactivity in response to either real-world or laboratory stressors will offer useful information regarding who may be at greatest risk of developing certain clinical conditions (e.g., heart disease) in the future. Thus, studies of cardiovascular risk factors often involve the assessment of physiological reactivity to stressors. Both under laboratory conditions (e.g., mental arithmetic, harassment, threat of shock) and in real-world settings (e.g., public speaking, driving, social interactions), behavioral stimuli have been shown to evoke pathogenic physiologic states. It is believed that the tendency to produce exaggerated physiological responses to stressful stimuli may be an index of coronary risk (see Kamarck & Jennings, 1991; Krantz & Manuck, 1984; Manuck, 1994; Pickering & Gerin, 1990; Treiber et al., 2003). In addition, exaggerated stress reactivity may serve as a contributor to disease or as a marker of pathogenic processes (e.g., atherosclerosis and ischemic heart disease), which have been correlated with the development of disease.

Commonly used methods of measuring the hemodynamic effects of stress include heart-rate and blood pressure monitoring. These are the most commonly used measures of physiological reactivity because they are practical, noninvasive, and reliable. Biochemical and neuroendocrine changes including elevated levels of circulating catecholamines and cortisol are also valid indicators of changes in stress response and have been

shown to be associated with hyperreactivity to stress (e.g., Eliot, 1987; Frankenhaeuser, 1983). Such indicators are measured through blood, urine, or salivary samples and thus are more invasive, time consuming, and costly to collect and assess. Given that individual responses have been shown to change in the presence of different stressors (Sherwood, Allen, Obrist, & Langer, 1986), the use of more sensitive measurements of cardiovascular functioning relative to sympathetic activity may be most desirable (e.g., de Geus, van Doornen, de Visser, & Orlebeke, 1990; Shulhan, Scher, & Furedy, 1986; van Doornen & de Geus, 1989). For example, the use of sensitive and specific measures of stress reactivity such as hemodynamic changes (e.g., peripheral resistance, cardiac output measured by impedance cardiography, circulating catecholamines, and cortisol levels) may provide a greater opportunity to evaluate mechanisms of change relative to stress response (e.g., de Geus et al., 1990).

For assessment of stress reactivity in naturalistic settings, researchers often make use of ambulatory monitoring devices such as ambulatory heart-rate monitors, accelerometers, and ECG recorders. These devices allow for objective data collection that allows for an assessment of the stress response to acute and chronic stressors in a free-living environment. For example, accelerometers can be attached to various locations on the body (e.g., trunk, thigh, shank) and represent a relatively noninvasive method of collecting continuous data on cardiac functioning. These devices recognize body postures (e.g., sitting, lying, standing) based on acceleration signals. Ambulatory heart-rate monitors and ECG recorders must be worn on the chest to allow for collection of cardiac activity data. Data are used to calculate variables (e.g., total energy expenditure) that provide information regarding activity level and metabolic expenditure over time. These calculations are used to translate continuous data into clinically meaningful information regarding functional capacity and changes in functioning over time. Ambulatory measurements of stress reactivity may be useful methods for identifying individuals who are at elevated risk for hypertension. In a 10-year follow-up study of stage 1 hypertensives, Georgiades, de Faire, and Lemma (2004) found that using 24-hour ambulatory blood pressure monitoring in conjunction with regular clinical outpatient blood pressure monitoring enhanced the likelihood of accurately identifying males at lower risk of developing hypertension at follow-up. The researchers thereby concluded that adding 24-hour ambulatory blood pressure monitoring as a standard clinical assessment tool may offer benefits in terms of decreasing patient anxiety, saving

physician time, and decreasing consumption of health care resources.

Measurement of Exposure to Psychosocial Stress

Measures of exposure to psychological stress typically focus on identifying environmental variables or triggers that result in utilization of various (adaptive or maladaptive) coping responses. Such measures include the Schedule of Recent Events (T.H. Holmes & Rahe, 1967) and the Survey of Recent Life Events (Kohn & Macdonald, 1992a, 1992b), which assesses an individual's exposure to a variety of common "hassles." The Survey of Recent Life Events was developed as an alternative to earlier measures (e.g., Daily Hassles Scale; Kanner, Coyne, Schaefer, & Lazarus, 1981), which were criticized for being contaminated by items, as well as a response format, that were thought to *reflect* subjective distress rather than *predict* it (Dohrenwend, Dohrenwend, Dodson, & Shrout, 1984; Dohrenwend & Shrout, 1985; Green, 1986; Kohn & Macdonald, 1992b). Measures of exposure to environmental stressors often utilize a Likert scale format, where the respondent is asked to indicate to what extent he or she feels a particular item/statement describes a part of his or her life during a specified period of time. Item responses are usually summed, with higher scores indicating a greater experience of perceived environmental stressors.

Other instruments evaluate psychological components of the stress response and include an assessment of cognitive and affective responses that are often associated with distress. For example, the Perceived Stress Scale (Cohen, Kamarck, & Mermelstein, 1983), a common measure of perceived distress, evaluates how unpredictable, uncontrollable, and overwhelming an individual believes events in his or her life to be. Other methods, such as stress diaries, ecological momentary assessments (Shiffman & Stone, 1998; Shiffman, Stone, & Hufford, 2008; Stone & Shiffman, 1994, 2002), and experience sampling (e.g., Myin-Germeys, van Os, Schwartz, Stone, & Delespaul, 2001; Simons, Gaher, Oliver, Bush, & Palmer, 2005), are used by many researchers to assess stress levels during daily activities. These methods often include external reminders to record diary information, thereby reducing retrospective recall bias (e.g., Cruise, Broderick, Porter, Kaell, & Stone, 1996; Shiffman et al., 2002; Shiffman, Paty, Gnys, Kassel, & Hickcox, 1996; Shiffman & Waters, 2004; Stone, Broderick, Schwartz, Shiffman, Litcher-Kelly, & Calvanese, 2003). The use of a stress diary allows important information to be collected, such as the nature of chronic stressors, mechanisms by which stressors

exert their effects, and the role that individual differences (e.g., personality, social, or environmental factors) play in the stress process. In addition, these strategies allow researchers to learn about what individuals perceive as stressful on a daily basis, patterns in reoccurring stressors, and other details regarding specific stressors such as patterns of responding.

Exercise as a Stress Reduction Technique

A vast body literature, including observational and interventional studies, examines the effects of exercise on stress reactivity and other aspects of emotional well-being (see Edenfield & Blumenthal, in press). Generally, cross-sectional methodologies compare physically fit persons to unfit counterparts, or active individuals to inactive/sedentary counterparts. Interventional studies, however, compare those who exercise to non-exercising controls before and after exercise training over a specified period of time. Their somewhat mixed findings are summarized below.

Cross-Sectional Investigations

Cross-sectional research generally has provided support for the idea that exercise may decrease stress reactivity for those who are classified as physically fit (e.g., Collier et al., 2008; D.S. Holmes & Roth, 1985; Light et al., 1987). It has been suggested that higher levels of physical fitness may allow individuals to recover more quickly following exposure to stress than less physically fit individuals (e.g., Cox, Evans, & Jamieson, 1979; D.S. Holmes & Cappel, 1987). However, some researchers argue that if baseline differences in anxiety and cardiovascular reactivity were consistently controlled, no differences would be evident relative to individual differences in fitness level (Plante & Karpowitz, 1987).

In a study of aerobic fitness in 72 female participants, D.S. Holmes and Roth (1985) found that the 10 most physically fit participants demonstrated smaller increases in heart rate during memory stress task performance than the 10 least fit participants. Interestingly, however, fitness level (based on a submaximal cycle ergometer test) had no impact on participants' subjective responses to the mental stress task (i.e., perceived stress in response to task). Similar results have been found in other studies, where lower cardiovascular reactivity (Light, Obrist, James, & Strogatz, 1987) and smaller increases in heart rate, DBP, and total peripheral resistance (Hull, Young, & Ziegler, 1984; van Doornen & de Geus, 1989) were demonstrated in more physically fit individuals in response to laboratory

stress tasks (e.g., mental arithmetic, emotionally unpleasant stimuli, reaction time tasks). In a recent investigation, Collier and colleagues (2008) evaluated the benefits of 4 weeks of aerobic versus resistance training on arterial stiffness, blood flow, and BP in unmedicated pre-hypertensive and stage 1 hypertensives (20 males, 10 females). The researchers reported that resting SBP decreased at similar rates following both interventions. However, increases in arterial stiffness (i.e., central and peripheral pulse wave velocity and vasodilatory capacity) were found following resistance training. Interestingly, a compensatory increase in blood flow was also found following resistance, which may offset the increase in arterial stiffness, according to the researchers. Nonetheless, these findings provide additional support for the contention that individuals with hypertension, or at risk of developing hypertension, should not rely solely on resistance training in an effort to improve cardiovascular functioning.

Steptoe, Kearsley, and Walters (1993) compared cardiovascular reactivity between 36 trained male athletes and 36 inactive (male) control counterparts. Cardiovascular response in relation to a mental stressor (i.e., public speaking task) following 20 minutes of exercise at varying levels of intensity (i.e., high intensity at 70% VO_2 max, moderate intensity at 50% VO_2 max, or light exercise control) was measured, and the researchers reported that the trained athletes demonstrated a hypotensive response following moderate- to high-intensity exercise. They also reported that both SBP and DPB were lower for the high-intensity exercisers than for controls during performance of the stress task. During recovery from the mental stressor, SBP was lower for high-intensity exercisers. As in other studies comparing extremely sedentary and active individuals (e.g., Roth, 1989), significant differences in body mass index (BMI) were found between groups; trained athletes demonstrated lower BMI than sedentary controls. Interestingly, however, the baseline difference in BMI did not moderate the observed post-exercise hypotensive effect.

Individuals with borderline BP elevations that are more physically fit have been found to demonstrate differential improvements in cardiovascular functioning in response to a mental stress task. For example, Perkins, Dubbert, Martin, Faulstich, and Harris (1986) found that borderline hypertensives classified as aerobically fit demonstrated smaller increases in both SBP and DBP than did their unfit counterparts. Sothmann, Horn, Hart, and Gustafson (1987) reported that physically fit participants showed a decrease in plasma nor-epinephrine following exposure to a stressor, although

no change in subjective mood status was reported by these individuals.

Some researchers have argued that changes in cardiovascular reactivity in response to stress are a product of individual differences in anger/hostility between physically fit and unfit individuals (e.g., Czajkowski, Hindelang, Dembroski, Mayerson, Parks, & Holland, 1990). In a study of cardiovascular reactivity in response to mild mental stress (i.e., video game, reaction time test, and 90-second cold pressor test) in a sample of competitive marathoners and their unfit but otherwise healthy counterparts, Dorheim, Ruddel, McKinney, Todd, Mellion, Buell, and Eliot (1984) found that distance running did not mitigate cardiovascular reactivity to behavioral stressors. In this study, the highly fit marathoners actually experienced greater elevations in cardiovascular reactivity (i.e., blood pressure) to mental challenges than did their unfit counterparts. The authors included an assessment of competitiveness (i.e., achievement motivation) in the study, with the expectation that individual differences on this variable might explain the unexpected findings; however, no differences in performance (e.g., work speed or correct responses) during mental challenges were observed between the two groups. It is possible that differences in reactivity may be explained by differences in how highly engaged participants were during the task. Another possible explanation for differences in reactivity is that fit individuals may exhibit physiological adaptations (e.g. upregulation of beta receptors) different from those of their unfit counterparts. In summary, it remains unclear to what degree fitness changes contribute to changes in cardiovascular reactivity over time.

Longitudinal Studies

Relatively few longitudinal studies of exercise training and cardiovascular reactivity to stress have been conducted. In one study of healthy coronary-prone (type A) males, Blumenthal, Emery, Walsh, Cox, Kuhn, Williams, and Williams (1988) found that aerobic exercise training resulted in more rapid recovery of heart rate, blood pressure, and myocardial oxygen consumption following completion of a mental arithmetic task. In 1990, using a similar methodology, this group assessed a new sample of coronary-prone males and found that aerobic versus anaerobic exercise (strength training) resulted in greater reductions in heart rate, DBP, and myocardial oxygen consumption. Levels of circulating epinephrine during recovery were also lower for those completing aerobic training. Interestingly, modality of exercise did not produce any significant differences

regarding cardiovascular reactivity in response to the stress task. Therefore, the researchers concluded that aerobic exercise produced overall changes in levels of blood pressure and heart-rate variability instead of immediate reduction of stress reactivity. In a follow-up study of participants from this initial cohort, only those type A males who were also identified as borderline hypertensive demonstrated the above-mentioned changes in cardiovascular reactivity (Sherwood, Light, & Blumenthal, 1989). In a similar study, Seraganian, Roskies, Hanley, Oseasohn, and Collu (1987) found exercise training to have no effect in type A men; however, it is important to note that this study excluded participants who were initially identified as demonstrating exaggerated psychophysiological activity.

Other studies have demonstrated similar findings relative to reductions in cardiovascular reactivity in response to laboratory stressors with aerobic exercise training. However, these studies have utilized less rigorous methodologies; thus additional caution must be taken in the interpretation of results. In investigations of borderline hypertensives, it has been shown that engaging in a low- to moderate-intensity aerobic exercise training program reduces blood pressure during laboratory stressors such as a Stroop color-work conflict stress tasks (Rogers, Probst, Gruber, Berger, & Boone, 1996) or a video game (Cleroux, Peronnet, & de Champlain, 1985). D. S. Holmes and McGilley (1987) reported that aerobically trained participants classified as unfit prior to study participation demonstrated a decrease in heart rate during a laboratory memory task. Although fitness level increased significantly for both groups in this study, the physically fit participants did not demonstrate the same results regarding decreased cardiovascular reactivity. D. S. Holmes and Roth (1987) also utilized a memory task to compare cardiovascular reactivity in response to aerobic and anaerobic exercise training. Results from this study showed that absolute heart rate during task performance was lower for aerobically trained participants, but that the groups did not show differences in reactivity to stress-induction procedures.

Findings are mixed regarding the impact of modality of exercise on cardiovascular reactivity to stress, and some investigations have demonstrated that no significant differences exist in cardiovascular reactivity between aerobic and anaerobic training programs. Sinyor, Golden, Steinert, and Seraganian (1986), for example, reported that no difference in heart rate or subjective reactivity to a series of mental stressors was demonstrated in a comparison of aerobic and anaerobic strength training. In a comparison of a 10-week cognitive-behavioral stress management program

(CBT), an anaerobic strength training program, and an aerobic training program with healthy type A males, Roskies, Seraganian, Oseasohn, Hanley, Collu, Martin, and Smilga (1986) found that the CBT intervention lowered reactivity. Those receiving the CBT stress management intervention demonstrated significant changes in behavioral reactivity (i.e., 13%–23% below baseline levels) compared to those who experienced the exercise conditions, which demonstrated comparable reductions in reactivity. The authors noted that changes in physiological reactivity were, in fact, minimal for all treatment groups and concluded that more research was needed to explore the relevance of physiological reactivity as an outcome measure for interventions with type A populations.

Overall, recent findings have been mixed regarding the role of changes in stress reactivity versus physical responsiveness to stressors. In a study of response to mental stressors (i.e., a speech task) following a 12-month exercise training intervention in caregivers, King, Baumann, O'Sullivan, Wilcox, and Castro (2002) reported that participants demonstrated significant reductions in BP. However, Georgiades et al. (2000) reported that no changes were found in stress-related BP responses following a 6-month exercise intervention in hypertensive individuals, despite reductions in absolute physical response (i.e., BP). Similarly, Steffen, Sherwood, Gullette, Georgiades, Hinderliter, and Blumenthal (2001) demonstrated absolute reductions in BP during exposure to daily life stressors following a 6-month exercise treatment program, although this study did not demonstrate stress-related BP responsiveness.

Consistent with theories purporting that participating in a level of exercise of greater intensity than what an individual is accustomed to may be less likely to improve responses and, in fact, has the potential to worsen subjective experiences (e.g., depressive symptoms; see Yeung, 1996), some studies have found that initial level of fitness may be a crucial factor regarding attenuation of physiological responses (e.g., de Geus et al., 1990). Similarly, some researchers have found cardiovascular reactivity to be greater in more physically fit participants than among their similarly active but less fit counterparts (de Geus, van Doornen, & Orleibenke, 1993). In addition, low-intensity training that does not result in increases in VO_2 max performance has also been shown to be more effective in decreasing cardiovascular reactivity to stressors relative to higher-intensity exercise that does demonstrate fitness improvements (Rogers et al., 1996).

Crews and Landers (1987) conducted a meta-analytic review of 34 studies investigating the impact of aerobic

training on reactivity to psychosocial stressors and concluded that aerobically fit individuals demonstrated reduced reactivity to psychosocial stressors, with an average effect size estimate of 0.48 ($p < .01$). In a more recent meta-analysis, Hamer et al. (2006) reviewed 15 RCTs examining the effect of a single session of aerobic exercise on BP in response to psychosocial laboratory tasks. Exercise interventions included in the studies reviewed ranged from mild-moderate (i.e., exercise intensity less than 60% VO_2 max or 75% heart-rate reserve) to vigorous (i.e., exercise intensity greater than or equal to 60% VO_2 max or 75% heart-rate reserve). Stress tasks utilized in the reviewed studies were the Stroop task, mental arithmetic, cold pressor task, and public speaking. The authors reported that participation in an acute bout of aerobic exercise of moderate to high intensity attenuated stress-related BP responses similar to those demonstrated in earlier meta-analyses that focused on forms of exercise training that are likely to produce fitness improvements (Crews & Landers, 1987). They concluded that the primary benefits of chronic exercise training may be explained by the possibility that habitual exercisers often encounter daily stressors more frequently during the post-exercise window, when an attenuated stress response would be most likely. More research is needed to improve our understanding of the relationship between exercise, physical fitness, and stress reactivity.

CARDIOVASCULAR DISEASE, PSYCHOLOGICAL HEALTH, AND EXERCISE

The majority of the available research suggests that psychological disorders (e.g., anxiety, depression, bipolar disorder, and schizophrenia) represent important cardiovascular risk factors. Patients with these psychological disorders have been shown to be at greater risk of cardiac morbidity and mortality than their counterparts in the general population (see Sowden & Huffman, 2009). Both behavioral and pathophysiological mechanisms have been proposed to explain this relationship, including increased prevalence of unhealthy behaviors (e.g., smoking, alcohol misuse, obesity, sedentary lifestyle, poor diet, poor treatment adherence) and known CVD risk factors (e.g., HTN, diabetes, metabolic syndrome) in mentally ill populations. Research has consistently demonstrated that individuals with various forms of psychological illness tend to lead mostly sedentary lives, which may further elevate risk for all-cause morbidity

and mortality (Richardson, Faulkner, McDevitt, Skrinar, Hutchinson, & Piette, 2005). Exercise may represent a form of behavioral activation that has particular utility for fostering decreases in a wide spectrum of depressive experiences, ranging from mildly depressed mood to clinical depression (see Carlson, 1991; Craft & Landers, 1998; North, McCullagh, & Vu Tran, 1990). As a result of consistent findings that exercise participation may produce mood improvements, the Centers for Disease Control and Prevention has recommended the inclusion of exercise as an adjunct to other empirically supported interventions for depression (Pate et al., 1995). Some researchers have also suggested that exercise alone may be an effective intervention for some individuals with depression (e.g., Craft & Landers, 1998; Netz, Wu, Becker, & Tenenbaum, 2005; Nicoloff & Schwenk, 1995). In general, exercise training has consistently been found to produce a reduction of symptoms of depression and anxiety (e.g., Biddle & Mutrie, 2001; Craft & Landers, 1998; Landers & Petruzzello, 1994; Long & Stavel, 1995; Martinsen, 1995; North et al., 1990; Petruzzello, Landers, Hatfield, Kubitz, & Salazar, 1991). Although discrepant findings exist, the evidence overwhelmingly supports the mood enhancement properties of exercise (Steptoe, Kimbell, & Basford, 1998; Yeung, 1996). The role that exercise may play in treating and preventing mental illness (e.g., depression), and in increasing the functional capacity in individuals with a preexisting psychological disorder, has been the subject of many investigations in recent years, and this data will be reviewed here.

Coronary Heart Disease and Depression

The relationship between depression and prognosis relative to CHD has been widely researched during recent decades (see Frasure-Smith & Lesperance, 2006). Thombs and colleagues (2006) reported that depression is 3 times more likely to occur in individuals who suffer an acute MI than in the general population, with an estimated 15%–20% of patients meeting criteria for a major depressive episode during their inpatient stay following MI. An even greater number of individuals demonstrate elevated symptoms of depressed mood that do not meet diagnostic criteria for a major depressive episode (Bush et al., 2005; R.M. Carney & Freedland, 2003; Lesperance & Frasure-Smith, 2000), and women may be at particular risk for depression following an MI (Mallik et al., 2006). Furthermore, depression has been identified as an independent risk factor for various adverse cardiac events, including CHD, angina, heart failure, MI, and overall cardiac mortality (R.M. Carney &

Freedland, 2003; Rutledge, Reis, Linke, Greenberg, & Mills, 2006).

Findings have consistently shown that individuals with cardiac disease are at elevated risk of developing depression (Egede, 2007), and that the development of depression or depressive symptoms is strongly associated with poorer prognosis in those with CHD (R. M. Carney et al., 2008; Frasure-Smith & Lesperance, 2005; Lett et al., 2004; Parashar et al., 2006; Pratt, Ford, Crum, Armenian, Gallo, & Eaton, 1996; Rugulies, 2002). Clinically depressed individuals who are otherwise identified as healthy are approximately 60%–80% more likely than non-depressed counterparts to develop CVD (Nicholson, Kuper, Hemingway, 2006; Rugulies, 2002; Wulsin & Singal, 2003). Evidence also supports a dose-response relationship, such that elevated depression severity is related to cardiac events that are more severe and occur more prematurely (Frasure-Smith & Lesperance, 2005; Rugulies, 2002). Some researchers have argued that the relationship between depression and poorer prognosis relative to CHD may be explained by cardiac disease severity, despite evidence that the relationship remains after numerous potential confounds are statistically controlled for (R. M. Carney & Freedland, 2003; Frasure-Smith & Lesperance, 2005; Lane et al., 2001; Lauzon et al., 2003; Mayou et al., 2000; Nicholson et al., 2006). Nonetheless, it is widely accepted that depression increases risk of subsequent cardiac events at least twofold during the first 12–24 months following an MI (Barth, Schumacher, & Herrmann-Lingen, 2004; Frasure-Smith & Lesperance, 2006; Lett et al., 2004; Rutledge et al., 2006). As a result, support is growing for the incorporation of assessment and treatment of depression and common psychiatric conditions (e.g., anxiety disorders) as a routine component of cardiac care. In fact, the most recently published American Heart Association guidelines (Lichtman et al., 2008) regarding comprehensive care for cardiac patients call for standard screening for depression and provision of treatment for depression to improve outcomes and treatment response.

Exercise and Depression

Prospective studies have repeatedly demonstrated that mostly sedentary individuals are more likely than their more active counterparts to endorse symptoms of depression (Camacho et al., 1991; Hassmen, Koivula, & Uutela, 2000; Ruuskanen & Ruoppila, 1995; Stephens, 1988). Moreover, when study participants increased physical activity from baseline levels, their risk of depression at follow-up was comparable to that of those individuals who were active throughout the study.

Interestingly, individuals who became more sedentary over time endorsed more depressive symptoms than those individuals who maintained participation in higher levels of physical activity (Camacho et al., 1991). Although these findings are important and provide further evidence supporting the general relationship between exercise and depression, cross-sectional methodologies are incapable of addressing the question of causality. Specifically, the question of whether leading a sedentary lifestyle causes depression, or conversely, whether depression results in decreased participation in physical activity or exercise, cannot be addressed by cross-sectional studies. More rigorous research designs (i.e., RCTs) designed to investigate the directionality of the relationship between exercise and associated changes in mental well-being are necessary to examine this issue.

Exercise training has been found to result in a decrease in symptom expression in individuals experiencing a wide array of depressive symptoms, ranging from nonclinical (i.e., normal, not depressed) to subclinical (i.e., presence of depressive symptoms not meeting criteria for a depressive disorder) and even clinical samples based on the criteria outlined in the text revision of the fourth edition of the *Diagnostic and Statistical Manual (DSM-IV-TR)* (American Psychiatric Association, 2000). In a number of rigorous RCTs evaluating exercise as a treatment for depressed mood, individuals who participated in the exercise training intervention consistently demonstrated more significant declines in depressive symptoms than controls. This relationship is demonstrated regardless of age, race, or gender (see Scully et al., 1998). However, some studies have shown that exercise may not result in significant mood improvements, and researchers have hypothesized that this limited effect is likely a result of a floor effect in the study sampled (e.g., King, Taylor, Haskell, & DeBusk, 1989; Moses, Steptoe, Mathews, & Edwards, 1989). Specifically, it may be extremely difficult to demonstrate significant decreases in depressive symptoms in a sample of individuals who are not suffering from significant symptoms upon enrollment in treatment. Studies of clinically depressed individuals (i.e., individuals meeting *DSM-IV-TR* criteria for major depressive disorder), however, may offer a more viable opportunity to observe changes in depressive symptomatology that result from exercise training.

Blumenthal and colleagues (1999) conducted an RCT evaluating the efficacy of exercise as a treatment for depression relative to a commonly used psychotropic medication (sertraline) and combination treatment (sertraline and exercise). The study sample consisted

of individuals who met criteria for major depressive disorder, as defined by the *DSM-IV-TR*. Participants were assigned to either a 16-week aerobic exercise intervention, a standard regimen of a selective serotonin reuptake inhibitor (SSRI) antidepressant medication (i.e., sertraline), or a combination treatment of exercise and sertraline. The exercise training protocol consisted of three sessions of monitored aerobic activity weekly for a total of 16 weeks. Participants in each treatment group experienced significant reductions in depressive symptoms, with no significant between-group differences. Thus, the investigators concluded that exercise may represent a viable treatment alternative for some individuals relative to psychotropic medication for depression. In 2000, Babyak and colleagues reviewed 10-month follow-up data for participants in the Blumenthal study. They reported that significantly lower rates of relapse were observed for those individuals who received the exercise-only intervention than for those who received antidepressant medication alone or the combination treatment. Of additional interest was the fact that the combined treatment (exercise plus sertraline) did not produce greater benefits than either treatment delivered independently.

Few RCTs have investigated the relative benefits of medication in comparison to exercise as treatment for depression. Interestingly, research has shown that when exercise is a component of treatment for individuals with psychological disorders, they tend to describe exercise as the “most effective” aspect of treatment (Martinsen et al., 1989; Porter, Spates, & Smitham, 2003; Sexton, Maere, & Dahl, 1989). In a recent study, Blumenthal and colleagues (2007) conducted a placebo-control study in which 202 adults (153 women and 49 men) diagnosed with major depressive disorder were randomly assigned to 16 weeks of either supervised group exercise, home-based unsupervised exercise, antidepressant medication (sertraline), or placebo pill. Following the 16-week intervention, 41 % of participants demonstrated a remission of symptoms (i.e., HAM-D score <8), with active treatment groups demonstrating the largest remission rates. Participants who completed 16 weeks of supervised exercise or sertraline demonstrated the highest rates of remission (45 % and 47 %, respectively). Individuals who received the home-based exercise treatment demonstrated the next highest remission rate (40 %), with individuals receiving placebo demonstrating the lowest rates of remission (31 %). Although no statistically significant differences were demonstrated between any of the treatments, these findings provide further evidence regarding the potential efficacy of exercise as a treatment for depression. The comparable antidepressant

effects demonstrated for exercise relative to sertraline are particularly important, as exercise may represent a more cost-effective, accessible, and acceptable means of treatment than more traditional forms of treatment for depression for some individuals.

Above and beyond providing a reduction in emotional distress when used as an individual treatment approach or coping strategy, exercise may be effective when used in adjunct with other interventions. The National Institute for Mental Health released a statement asserting that regular physical exercise may be useful as an adjunct form of treatment for many psychological disorders (Morgan & Goldston, 1987). Farmer, Locke, Moscicki, Dannenberg, Larson, and Radloff (1988) reported that females who were minimally active were twice as likely as females engaging in more exercise to meet criteria for clinical depression over the course of an 8-year follow-up study. Similarly, sedentary males were more likely to maintain a state of depression. Similar findings were demonstrated in a study utilizing a 10- and 20-year follow-up protocol (Camacho et al., 1991) for males and females who were classified as clinically depressed. In this study, sedentary males and females were found to be at significantly higher risk of becoming depressed than individuals who participated in a regular program of moderately strenuous exercise (i.e., three 30-minute sessions per week of jogging or cycling at 75 %–80 % heart-rate reserve). In an epidemiological survey of college-aged males, Paffenbarger, Lee, and Leung (1994) found that depression rates were lower among physically active individuals (including those involved in competitive sports) than among their more sedentary counterparts.

As mentioned earlier, exercise may have more prominent mood enhancement effects for individuals reporting higher levels of initial depression (e.g., Gauvin, Rejeski, & Norris, 1996). This assertion is consistent with findings suggesting that behavioral activation (Jacobson, Dobson, Truax, & Addis, 1996; Lejuez, Hopko, & Hopko, 2001; Martell, Addis, & Jacobson, 2001) may represent an adequate single-component treatment for clinical depression. Such findings are also consistent with research that has demonstrated the benefits of cognitive-behavioral psychotherapeutic interventions, which pair behavioral activation with cognitive restructuring exercises, to be most evident during the early phases of treatment, when behavioral foci are more prominent (Beckham & Leber, 1995; Hollon, Shelton, & Davis, 1993; Otto, Pava, & Sprich-Buckminster, 1996). Given the ongoing debate in the literature regarding the effectiveness of psychotherapeutic interventions in moderate to severe cases of depression (e.g., see Elkin

et al., 1989, on findings that medication is most effective in severe cases of depression), these findings are particularly interesting.

In a meta-analysis of 14 RCTs investigating the efficacy of exercise as a treatment for major depressive disorder, Lawlor and Hopker (2001) noted that exercise training is more effective in reducing symptoms of depression than no treatment. More importantly, perhaps, the researchers noted that exercise training produces antidepressant benefits similar to what is seen in individuals receiving cognitive therapy for depression. However, the authors concluded that the full extent of the effectiveness of exercise as a treatment for depression could not be determined due to various methodological shortcomings of the majority of the studies in their meta-analysis. In a more recent meta-analysis, Stathopoulou, Powers, Berry, Smits, and Otto (2006) examined 11 exercise intervention studies, 4 of which were published after the Lawlor and Hopker meta-analysis. Conclusions from this review indicated that exercise may be considered an effective intervention for depression relative to control conditions. Despite the methodological limitations of some studies, the authors suggested that the existing evidence has consistently supported exercise as a viable treatment for depression.

Other Psychiatric Disorders and CVD

Although the majority of the literature has focused on the relationship between depression and heart disease, anxiety disorders, schizophrenia, and bipolar disorder have also been identified as significant risk factors for the onset and exacerbation of CVD. Unfortunately, psychiatric illnesses in cardiac patients frequently go undiagnosed and untreated, despite the known detrimental impact that these conditions have on morbidity and mortality rates. Anxiety symptoms that do not meet criteria for an anxiety disorder, as defined by the *DSM-IV-TR* (American Psychiatric Association, 2000), are common following acute cardiac events. An estimated 20%–25% of post-MI patients experience anxiety symptoms that persist and are diagnosable at a later time (Crowe, Runions, Ebbesen, Oldridge, & Streiner, 1996; Moser, 2007; Suls & Bunde, 2005). Although findings are mixed regarding the relationship between subclinical anxiety and CVD, the majority of research findings suggest that anxiety has a detrimental effect on CVD-related mortality (Allgulander & Lavori, 1991; Eaker, Sullivan, Kelly-Hayes, D'Agostino, & Benjamin, 2005; Kawachi, Sparrow, Vokonas, & Weiss, 1994; Moser, 2007). In addition, the presence of anxiety in cardiac patients has been shown to increase in-hospital complications

following an acute cardiac event and may also contribute to continued ischemic events, reinfarction, and other adverse cardiac events (Moser, Riegel, McKinley, Doering, An, & Sheahan, 2007; Shen et al., 2008; Shibeshi, Young-Xu, & Blatt, 2007).

Anxiety Disorders

Specific anxiety disorders (e.g., generalized anxiety disorder and panic disorder) are also associated with adverse cardiac events. In particular, generalized anxiety disorder, a condition characterized by chronic and excessive worry, difficulty controlling worry, and distress and/or functional impairment associated with these symptoms, has been shown to be associated with elevated rates of various CVD risk factors (e.g., smoking, hypercholesterolemia, diabetes; Barger & Sydeman, 2005). In addition, generalized anxiety disorder has recently been shown to predict major cardiac events in CAD patients (Frasure-Smith & Lesperance, 2008). Other anxiety disorders that have been associated with CVD-related morbidity and mortality include post-traumatic stress disorder, which occasionally occurs following a severe cardiac event (Pedersen, 2001); phobic anxiety, which may place affected individuals at particular risk of sudden cardiac death (Watkins, Blumenthal, Davidson, Babyak, McCants, & Sketch, 2006; Kawachi, Colditz, Ascherio, Rimm, Giovannucci, Stampfer, & Willett, 1994); and panic disorder. Panic disorder is characterized by chronic and recurrent panic attacks associated with various physical symptoms that may mimic cardiac symptoms, anticipatory anxiety about future attacks, avoidance behaviors, and a fear of adverse physical consequences associated with acute symptoms (American Psychiatric Association, 2000). Panic disorder has been estimated to occur in 10%–50% of CVD patients (Fleet, Lavoie, & Beitman, 2000) and may place an affected individual at 3–4 times greater risk of MI than the general population (Smoller, Pollack, Wassertheil-Smoller, Jackson, Oberman, Wong, & Sheps, 2007). Common treatments for anxiety disorders include SSRIs and benzodiazepines, and these agents do not appear to have any significant negative cardiac side effects (Feighner, 1999; Huffman & Stern, 2003). Although most studies support a relationship between anxiety (clinical and subclinical forms) and increased risk for CVD-related mortality, more research is needed to further clarify this relationship.

Bipolar Disorder and Schizophrenia

Bipolar disorder and schizophrenia occur far less frequently in the general population than depressive and

anxiety disorders, with estimated lifetime prevalence rates of 1%–3% for bipolar disorder (type 1) and 1% for schizophrenia (American Psychiatric Association, 2000). However, individuals with these disorders die younger than their unaffected peers, often due to increased prevalence of medical comorbidities, with a large degree of this excess in mortality associated with CVD-related conditions (Angst, Stassen, Clayton, & Angst, 2002; C.P. Carney & Jones, 2006). Individuals with bipolar disorder are believed to be at least twice as likely to die from cardiovascular causes as individuals in the general population (Osby, Brandt, Correia, Ekblom, & Sparen, 2001). Similarly, individuals with schizophrenia have an estimated life expectancy that is 10–15 years shorter than unaffected individuals (Newman & Bland, 1991), with an estimated 20% of deaths in schizophrenic patients attributed to CVD (Ryan & Thakore, 2002). In addition, medications commonly used to treat both disorders (e.g., lithium, antipsychotics) are heavily associated with various CVD risk factors, including weight gain, ventricular arrhythmia, diabetes, and hyperlipidemia (Baptista, Kin, Beaulieu, & de Baptista, 2002; Baptista et al., 1995). The mechanisms thorough which psychotropic treatments for these disorders affect cardiac outcomes is poorly understood; thus more research is needed to improve treatment of these individuals. In addition, more research is needed relative to the incidence of various psychological disorders in cardiac patients, and the role that improved assessment and treatment practices may play in improving CVD-related outcomes in these individuals.

THE ROLE OF EXERCISE IN TREATING ANXIETY DISORDERS AND SEVERE MENTAL ILLNESS

As reviewed above, the majority of studies investigating the emotional benefits of exercise have focused on the widely accepted antidepressant effects that have been found with exercise training. However, some data support exercise as an effective intervention for other conditions, such as anxiety disorders and other more chronic and severe forms of mental illness (e.g., bipolar disorder, schizophrenia). For example, early uncontrolled studies suggest that phobias may be treated successfully through exposure to a phobic stimulus following exhaustive exercise (Driscoll, 1976; Muller & Armstrong, 1975; Orwin, 1973). Acute exercise has also been found to reduce self-reported symptoms of state anxiety (see Petruzzello et al., 1991) and panic symptoms (Rejeski,

Hardy, & Shaw, 1991). It has also been found that individuals with panic disorder symptoms tolerate aerobic exercise as well as healthy controls (i.e., demonstrate physiological responses no greater than those produced by normal controls; Rief & Hermanutz, 1996; Stein et al., 1992), although subjective experiences of anxiety may be higher in panic patients than in healthy controls (Cameron & Hudson, 1986). Other investigations have highlighted the impact of exercise on anxiety sensitivity, or fear of physical sensations that are perceived as anxiety (e.g., increased heart rate, shallow or rapid breathing), which may precipitate panic attacks (Ehlers, 1995). In a study of exercise-induced physiological arousal relative to anxiety sensitivity, Broman-Fulks, Berman, Rabian, and Webster (2004) found that participation in both low-intensity exercise (i.e., walking at 1 mph on a treadmill) and high-intensity exercise (i.e., walking or jogging on treadmill at a pace sufficient to achieve heart rate of 60%–90% of the age-adjusted predicted maximum heart rate) reduced anxiety sensitivity. Importantly, it was observed that participation in high-intensity exercise resulted in a more rapid decrease in anxiety sensitivity scores.

Cognitive theories attempt to explain the relationship between exercise training and decreased anxiety (and anxiety sensitivity), suggesting that exercise may facilitate a benign attribution of arousal produced by a phobic stimulus. According to this theory, exercise would, thus, prevent the maladaptive, fear-induced response experienced in panic from occurring (Clark, 1986), which may also place affected individuals at lower risk for sudden cardiac death, as discussed above. It has also been suggested that exercise training may represent an exposure technique, which is a typical component of cognitive-behavioral therapies for anxiety disorders. Exposure therapy involves intentionally inducing a feared bodily sensation in the absence of severe negative consequences (e.g., panic attack). Based on this theory, it is possible that exercise training may be a viable treatment for individuals who suffer from panic attacks in that it reduces anxiety sensitivity (Broman-Fulks et al., 2004). Additional research is needed to further our understanding of how to utilize exercise interventions in the treatment of more chronic and severe anxiety conditions (e.g., panic disorder, GAD). In addition, research addressing issues of a possible dose-response relationship relative to the anxiolytic benefits of exercise is needed. Moreover, studies that have investigated physiological adaptations in both healthy and depressed samples should be replicated in anxious samples so that the psychological benefits of exercise across common psychiatric conditions may be better understood.

Although few investigations have examined the effect of exercise in treating more chronic and severe forms of mental illness (e.g., bipolar disorder, schizophrenia), the available data suggest that exercise may decrease psychotic hallucinations (Falloon & Talbot, 1981) and depression in the context of severe mental illness (e.g., Faulkner & Biddle, 1999; Pelham, Campagna, Ritvo, & Birnie, 1993). In a recent study, Kilbourne, Rofey, McCarthy, Post, Welsh, and Blow (2007) performed a cross-sectional analysis of exercise and nutrition behaviors for patients enrolled in the VA's National Psychosis Registry (Blow, McCarthy, & Valenstein, 2000). They consisted of 6,710 VA patients who either were classified as free of severe mental illness (46%) or met criteria for bipolar disorder (29%) or schizophrenia (26%) during fiscal year 1999. All participants had completed the VA's Large Health Survey of Veteran Enrollees subsection on health and nutrition behaviors. The researchers reported that individuals with bipolar disorder or schizophrenia reported less healthy nutritional habits (e.g., eating only one meal per day, more difficulty obtaining or preparing food) more often than the group without severe mental illness. Interestingly, patients with bipolar disorder reported poorer exercise habits (e.g., walking fewer than 3 days per week) and recent weight gain (i.e., 10 pounds during the previous 6 months) more often than schizophrenia and participants who did not have severe mental illness. These findings seem to suggest that individuals with bipolar disorder may be more vulnerable than other patients with severe mental illness to adverse consequences associated with poor nutrition and exercise habits, such as CVD-related conditions.

Pharmacological treatments remain the standard of care for most chronic and severe forms of mental illness, including bipolar disorder (e.g., lithium, depakote) and schizophrenia (e.g., atypical antipsychotics); thus most research has emphasized biological mechanisms and pharmacological interventions for these conditions. However, a few studies have investigated the effect of exercise as a treatment for individuals with bipolar disorder, and findings suggest that compliance with a prescription of low-intensity exercise (i.e., walking 30 minutes, 4 times per week for 4 weeks) followed by independent maintenance of this program resulted in an increase in the use of adaptive coping strategies at post-test assessment. Longer-term follow-up data (at 1, 3, and 6 months) suggested that decreased frequency of exercise participation resulted in a greater level of depressive symptoms reported, particularly for those who participated in 4 weeks of prescribed (versus elective initiation) exercise during treatment (Edenfield, 2007).

These findings suggest that a prescription for mild- to moderate-intensity exercise may have an important impact on an individual's perception of, and response to, stressful life events. In addition, self-maintained exercise subsequent to participation in a 4-week program of prescribed exercise may serve to prevent the worsening of depressive symptoms over time.

Ng, Dodd, and Berk (2007) completed a retrospective cohort analysis of patients diagnosed with bipolar disorder who were admitted to a private psychiatric hospital over a 2-year period. Patients were invited to participate in a voluntary exercise program (i.e., walking group) during admission and were stratified into two groups (exercise versus non-exercise) based on activity selection (e.g., exercise, art therapy, relaxation, music therapy, psychoeducation, or group discussions) following admission. Researchers reported that those who participated in the walking program ($N = 24$) had significantly lower scores on a self-report measure of illness severity (the Depression Anxiety Stress Scale; Lovibond & Lovibond, 1995) at discharge. However, clinician-rated symptom severity did not differ between groups. Despite significant limitations of this study (e.g., small sample, no randomization or control for confounding variables, no control for subtype of bipolar disorder), findings suggest that exercise participation may assist in reducing perceived levels of symptom severity for some individuals with bipolar disorder. More research is needed to investigate the role of exercise as an adjunctive component of a more comprehensive intervention for bipolar disorder. This research should include RCTs, so that the effect of exercise on symptom improvement in bipolar disorder may be addressed. Moreover, studies investigating the role of interventions targeting improved nutritional and exercise behaviors, and the unique psychosocial challenges faced by those with severe mental illness (e.g., social support and financial considerations, medication side effects), should be performed.

ADHERENCE TO LIFESTYLE BEHAVIOR CHANGES

Even the most effective therapy prescribed by the most careful and diligent clinician can only be effective if a patient is compliant with the treatment recommendations. Motivation tends to improve when patients have positive experiences with their clinicians, thus establishing stronger trust in their provider and the therapeutic relationship. Despite the well-known benefits

of both pharmacological and lifestyle interventions for HTN, noncompliance represents a significant problem, with as many as 50% of patients discontinuing antihypertensive medications within 1 year after initiation (Jones, Gorkin, Lian, Staffa, & Fletcher, 1995). In addition, initiation and maintenance of regular exercise programs and dietary modifications may prove to be even more difficult. Various psychological and behavioral theories have attempted to explain challenges relative to adherence. For example, the health belief model (Rosenstock, 1974) posits that adoption of new health-related behaviors is determined by an individual's beliefs about his or her health (e.g., illness vulnerability, severity of illness), as well as the proposed behavior change (e.g., barriers to behavior, possible benefits of behavior). Bandura's (1986) social cognitive theory posits that behavior change may be predicted by individual expectations regarding outcome and self-efficacy. According to this theory, self-efficacy, or an individual's confidence in his or her ability to perform a given behavior, is thought to represent the stronger predictor of adherence and is influenced by mastery experiences, modeling, social persuasion, and somatic or emotional states (Bandura, 1977). According to the theory of planned behavior (Ajzen, 1988, 1991, 2002; Ajzen & Fishbein, 1980), the most viable predictor of behavior change is intention, or how determined an individual is to change a given behavior. Possibly the most commonly referenced theory of behavior change is Prochaska and DiClemente's (1983) transtheoretical model. This theory emphasizes stages of motivation or readiness for change and proposes five stages of change: (1) pre-contemplation (behavior change is not being considered); (2) contemplation (behavior change is considered, but no action is taken); (3) preparation (small, intermittent behavior changes may be seen); (4) action (behavior change is engaged for less than 6 months); and (5) maintenance (behavior change is engaged for 6 months or more). Individuals are said to fluctuate between each of the stages, with progression influenced by various factors such as self-efficacy, perceived cost/benefit of behavior change, and readiness for change. In general, there are various factors that influence behavior change. In addition to psychological theories, which have been supported as predictors of dietary and exercise behaviors (e.g., higher self-efficacy predicts exercise adherence in healthy sedentary adults; Oman & King, 1998), other predictors including mood, social support, and environmental factors exist. More research is needed to better understand predictors of, and barriers to, adherence to behavior change and health outcomes.

Exercise Adherence

As mentioned above, long-term adherence to an exercise regimen is typically low. Data from the National Exercise and Heart Disease Project suggest that although exercise participation resulted in somewhat lower mortality rates, the differences between exercisers and non-exercising controls were not significantly different (Shaw, 1981). However, in studies where participants demonstrated higher adherence rates to exercise training, researchers report significant decreases in relative risk of mortality and other important end points (e.g., rate of hospitalization; Belardinelli, Georgiou, Cianci, & Purcaro, 1999).

Rates of non-adherence to exercise may be even higher for individuals suffering from depression, as some symptoms of depression (e.g., fatigue, anhedonia, social withdrawal) may act as an added barrier to exercise initiation or maintenance. Consistent with this theory, research has shown that individuals reporting a higher level of depression upon enrollment in cardiac rehabilitation participated in fewer exercise sessions and dropped out of the program at higher rates than participants endorsing fewer depressive symptoms (Glazer, Emery, Frid, & Banyasz, 2002). Assessing motivation to exercise prior to enrollment in a program of exercise training may be a useful way to improve adherence (Marcus & Forsyth, 2003), as motivation is thought to be a critical aspect of behavior change. Studies that have investigated the effect of a brief counseling intervention matched to an individual's motivation level have found that such an intervention improves one's ability to achieve defined exercise goals (Bock, Marcus, Pinto, & Forsyth, 2001). This approach requires clinicians to review lapses in exercise participation with patients so that unique barriers and motivators relative to adherence may be determined. Meta-analyses of diet and exercise interventions have found that behavior change may be effectively produced (Brunner, White, Thorogood, Bristow, Curle, & Marmot, 1997; Dishman & Buckworth, 1996), particularly when strategies such as behavioral contracting, positive reinforcement, stimulus control, contingency planning, and external reminders are used (for reviews, see Brownell & Cohen, 1995; Burke, Dunbar-Jacob, & Hill, 1997; Dunbar-Jacob & Schlenk, 2001). Additional research is needed to explore the relationship between various psychological variables and exercise adherence, as individual differences in anxiety and life satisfaction are thought to be associated with dropout from exercise participation in some populations (e.g., Herman, Blumenthal, Babyak, Khatri, Craighead, & Krishnan, 2002).

SUMMARY AND FUTURE DIRECTIONS

The field of behavioral cardiology has grown out of the need to address the various psychosocial risk factors of CVD onset and exacerbation that have been identified, including stress and stress reactivity, various psychological illnesses, and lifestyle behaviors (e.g., eating patterns, weight, smoking, alcohol use). It has become so widely accepted that psychosocial variables play a critical role in CVD (incidence and treatment) that the American Heart Association now recommends regular screening for and treatment of depression in cardiac patients (Lichtman et al., 2008). Although numerous studies have supported the relationship between lifestyle factors and cardiac risk factors, including hypertension, few investigations utilizing rigorous methodology (i.e., RCTs) have examined the effect of lifestyle modification interventions in individuals at risk of developing cardiovascular disease. Rigorous randomized, controlled designs that use careful medical screening, precise documentation of cardiac risk factors (e.g., hypertensive status), reproducible interventions, and adequately powered samples are imperative to the advancement of the literature on the importance of integrative cardiovascular care. Such studies should also consider individual differences, as there appears to be considerable variability in response to treatment, such that the target for lifestyle modification may differ between patients (e.g., tobacco cessation, weight loss). Identification of the aspects of treatment that are needed for a given subgroup of patients is an important avenue for future research to pursue to enhance individualization of treatment, which is expected to increase treatment adherence and, ultimately, effectiveness. In addition, mechanisms of change that may offer information regarding which lifestyle modifications demonstrate the most significant positive impact on cardiac risk factors (e.g., reduction of BP, decreased stress reactivity), and for what subgroups of the population, are other important targets for future investigations. Development, implementation, and evaluation of various lifestyle modification interventions are critically important to treatment and prevention efforts relative to cardiovascular disease and associated risk factors (e.g., hypertension, obesity, psychological illnesses).

Another important area that warrants ongoing research is the relationship between exercise, stress reactivity, psychological well-being, and incidence of CVD. Enhancing our understanding of the complex relationship between these variables is essential to improving public health initiatives, particularly in light of the high

cost of sedentary lifestyles, including increased health care costs and overall morbidity and mortality rates. Exercise may represent a clinical intervention strategy important to the treatment and prevention of various disease processes, including the onset or relapse of psychological conditions (e.g., depression, anxiety). In addition, exercise may offer a method for ameliorating the effects of stressors that occur in an individual's life (Salmon, 2001), which is particularly relevant for individuals who are already suffering functional impairments associated with psychopathology. Moreover, exercise has the potential to moderate some health consequences commonly associated with serious mental illness (e.g., bipolar disorder, schizophrenia), such as obesity, diabetes, and hypercholesterolemia, which likely result from a combination of unhealthy lifestyle behaviors and the side effects of pharmacological agents used to manage these conditions. Overall, exercise may represent a more accessible and acceptable treatment option for some populations, particularly for individuals who are resistant to more traditional therapies or to whom traditional therapies are not available as a result of cultural, financial, or other personal factors. Further research investigating the differential benefits of various forms of stress-management treatments (e.g., exercise, relaxation training, meditation, psychotherapy), as well as investigations of the efficacy of such interventions in various subgroups of the population for whom exercise may represent a viable treatment option (e.g., coronary-prone individuals), is needed. In addition, further investigation of the dose-response relationship relative to the psychological benefits of exercise is needed. This line of research would provide insight regarding the effectiveness of exercise as a treatment for stress-related disorders and would also provide information necessary to improve our understanding of who may experience the greatest benefits of exercise and other behavioral/lifestyle interventions that may be used in the treatment of various health conditions.

Exercise Psychotherapy

Denise Dixon

Exercise has been described as a fundamental component of the “healing power of nature” since the time of Hippocrates, along with proper nutrition, adequate rest, fresh air, massage, and baths (W.H.S. Jones, 1953). Hippocrates and other medical philosophers acknowledged the merits of exercise, albeit without a scientific rationale for the underlying mechanisms. Both the industrial revolution in the 20th century and advances in technology in the 21st century, which resulted in a sociocultural shift from hard physical labor to sedentary living, have been accompanied by physical and mental health comorbidities, such as alarming increases in the prevalence in obesity and depression (control over infectious diseases notwithstanding; Johnsgard, 2004).

While exercise to improve physical and mental health has been prescribed for quite some time, exercise psychotherapy represents a relatively recent modality of therapy for the presentation of mood, anxiety, and other mental health disorders, as well as for the presentation of primary or comorbid medical conditions, such as obesity, diabetes, and heart disease. This chapter provides definitions regarding exercise psychotherapy and a more in-depth discussion regarding the theoretical underpinnings, assessment and measurement tools, and practical implications of exercise psychotherapy as a modality of treatment for physical and psychological health problems. Practical guidelines are provided for the clinical application of exercise psychotherapy for the prevention and treatment of physical and mental health problems, including guidelines regarding the

ethical practice of exercise psychotherapy. While the terms “client” and “patient” have long been used interchangeably among mental health practitioners, here the term “client” will be used for persons seen in outpatient psychotherapy, and the term “patient” will be used for individuals with medical illness or more severe psychopathology (Hays, 1999).

WHAT IS EXERCISE PSYCHOTHERAPY, AND HOW DOES IT DIFFER FROM PSYCHOTHERAPY AND EXERCISE INTERVENTIONS?

Exercise is defined as the exertion of the body, with the aim of achieving a beneficial level of fitness and health, both physically and mentally (Merriam-Webster, 2003). It has also been defined as the act of employing or putting into play; activity that requires physical or mental exertion, especially when performed to develop or maintain fitness; “to bring to bear,” or to exert; “to implement the terms of (as an option)”; and “to use repeatedly in order to strengthen or develop” (Merriam-Webster, 2003). Exercise involves either active or passive exertion of small or large areas of body muscle mass, sometimes challenging either the anaerobic or aerobic metabolic system, or both (Sime, 2002). There are three different intensities of exercise: light, moderate, and vigorous (Hays, 1999; Johnsgard, 2004;

Sime, 2002; Tremblay, Simoneau, & Bouchard, 1994). Light exercise typically permits an individual to talk simultaneously. Forms of light exercise include walking, light housework, gardening, and gentle stretching. Moderate exercise typically requires increased exertion, so that the individual feels slightly out of breath. Examples of moderate exercise are brisk walking or walking up hills, yoga, and Pilates. Vigorous exercise necessitates more rapid breathing and increased and sustained levels of exertion, such as running or jogging, cycling, swimming, and weight or strength training (Hays, 1999; Johnsgard, 2004; Sime, 2002; Tremblay et al., 1994). Exercise may be purely functional, in the form of daily activities of living, such as walking, lifting, pushing, or climbing stairs. Physical activity may also take the form of a variety of enjoyable play-type, recreational, or leisure activities, the inherent pleasure of which may be sufficient to maintain the behavior indefinitely (Hays, 1999; Johnsgard, 2004; Sime, 2002).

Psychotherapy is the "treatment of mental or emotional disorders, or of related bodily ills by psychological means," or a set of techniques believed to cure or to help solve behavioral and other psychological problems in humans, the common element of which is direct personal contact between therapist and patient, mainly in the form of talking (Merriam-Webster, 2003). Exercise therapy (or therapeutic exercise) is defined as the use of exercise as an adjuvant treatment modality to improve physical and/or mental health outcomes (Daley, Copeland, Wright, Roalfe, & Wales, 2006; Hays, 1999; Johnsgard, 2004; Sime, 2002; Tkachuk & Martin, 1999), or as the prescription of a physical activity program in which the client undertakes voluntary muscle contraction and/or body movement with the aim of relieving symptoms, improving function, or retaining or slowing the deterioration of health (N.F. Taylor, Dodd, Shields, & Bruder, 2007). Therapeutic exercise has been used for individuals suffering from a plethora of medical and psychological health problems, including obesity, diabetes, cardiac disease, cancer, multiple sclerosis, osteoarthritis, depression, and anxiety (Annesi & Unruh, 2008; Babyak et al., 2000; Blumenthal et al., 2007; Conn, Hafdahl, Minor, & Nielsen, 2008; Conn, Hafdahl, Porock, McDaniel, & Nielsen, 2006; Daley et al., 2006; Dishman et al., 2006; Dunn, Trivedi, Kampert, Clark, & Chambliss, 2002, 2005; Friedenreich & Cust, 2008; Graham, Kremer, & Wheeler, 2008; Halle, Korsten-Reck, Wolfarth, & Berg, 2004; Hernández-Molina, Reichenbach, Zhang, Lavalley, & Felson, 2008; Kangas, Bovbjerg, & Montgomery, 2008; Kelly, Steinberger, Olson, & Dengel, 2007; Kruk, 2007; Lee & Russell, 2003; Pradhan, Manson, Rifai, Buring, &

Ridker, 2001; Qi, Hu, & Hu, 2008; N.F. Taylor et al., 2007; Zhang et al., 2007).

While exercise therapy may involve the mental health care practitioner (e.g., psychologist, psychiatrist, social worker) engaging in exercise (such as walking) on an intermittent basis, descriptions of exercise therapy tend to focus on the practitioner facilitating the initiation and maintenance of habitual exercise for the client for the prevention and treatment of physical and/or mental health conditions, outside the regularly scheduled therapy sessions (Hays, 1999; Johnsgard, 2004; Sime, 2002). Exercise therapy has been described as an active intervention that necessitates that the client or patient conquer inertia (to initiate motion), choose a physical activity in which to engage (as well as the time, location, and duration of the activity), and sustain the effort to engage in the chosen physical activity, despite transient physical discomfort (Hays, 1999; Johnsgard, 2004; Sime, 2002). Therapeutic exercise has been determined most likely to be effective when relatively intense, and there are indications that targeted and individualized exercise programs may produce more beneficial outcomes than standardized programs (N. F. Taylor et al., 2007).

Exercise therapies and interventions have remained marginally distinct from exercise psychotherapy (also known as walk/talk therapy). Exercise psychotherapy has been described as the practice of integrating a program of exercise with traditional psychotherapy, as a primary or adjuvant treatment modality for mental and/or physical illness (Hays, 1999; Johnsgard, 2004). Exercise psychotherapy is unique in that the practitioner (who typically has expertise in exercise psychology and physiology) exercises (typically walking) with the client during the treatment session (Hays, 1999). Through this process, the therapist is a consultant, providing exercise prescriptions, support, encouragement, and/or technical advice (Hays, 1999), and acting as a role model in demonstrating his or her use of exercise as a mechanism for preventing and treating mood disturbances, as well as a means of appreciating and connecting with nature/beauty (Sime, 2002), and as a participant in the therapeutic process (Hays, 1999). The mental health practitioner typically recommends that the client engage in additional exercise sessions on his or her own, between therapy sessions, with the goal of establishing a regular pattern of exercise that can continue following the eventual termination of therapy (Hays, 1999; Johnsgard, 2004). The therapist typically focuses on the enjoyment of the exercise, in addition to reducing emotional disturbance. Walking briskly side by side with clients has been noted to facilitate engagement in the

therapeutic process, particularly with guarded patients or during the discussion of difficult topics (Hays, 1999; Johnsgard, 2004). The side-by-side (versus face-to-face) orientation has been depicted as less threatening to clients, thus allowing the therapist to approach difficult topics without the additional pressure of direct and continuous eye contact (Hays, 1999; Johnsgard, 2004). Exercise may provide a welcome distraction (via motor activities) for some clients, who may report that their minds clear enough to allow them to listen and process information more effectively, thus making them more receptive to therapeutic suggestions (Hays, 1999; Johnsgard, 2004). The physical exertion associated with brisk walking has been described as increasing creativity and problem solving on both the part of the therapist and the client, and patients describe the constantly changing scenery during the walk as refreshing (Hays, 1999; Johnsgard, 2004). The option of gazing at the scenery or focusing on the pace or rhythm of the walking stride may help to create an informal atmosphere, thus facilitating more spontaneous responses (Hays, 1999; Johnsgard, 2004). The informal nature of the walk may also facilitate candor and reduce guardedness (Kendzierski & Johnson, 1993). Despite the noted benefits of exercise for psychological and physical health outcomes, exercise therapies have been described as the “neglected intervention” in mental health care (Callaghan, 2004), and little empirical research has been conducted to support their efficacy.

Effects of Exercise on Physical Health

Voluntary physical activity and exercise training have been demonstrated to positively influence brain plasticity by facilitating neurogenerative, neuroadaptive, and neuroprotective processes, which are mediated by neurotrophic factors (Dishman et al., 2006). The adaptations in the central nervous system associated with exercise training and physical activity have implications for the prevention and treatment of obesity, cancer, depression, the decline in cognition associated with aging, and neurological disorders such as Parkinson’s disease and Alzheimer’s disease, among other conditions (Bergen, Toole, Elliott, Wallace, Robinson, & Maitland, 2002; Blumenthal et al., 2007; Cakit, Saracoglu, Genc, Erdem, & Inan, 2007; Campbell & McTiernan, 2007; Daley et al., 2006; Dishman et al., 2006; Friedenreich & Cust, 2008; Halle et al., 2004; Hu, Lakka, Kilpeläinen, & Tuomilehto, 2007; Lautenschlager et al., 2008; Salmon, 2001; Stevens & Killeen, 2006; Yu, Kolanowski, Strumpf, & Eslinger, 2006). Chronic voluntary physical activity also has been shown to attenuate neural responses to stress

in brain circuits responsible for regulating peripheral sympathetic activity (Campbell & McTiernan, 2007; Ströhle et al., 2007; Timmons, Tarnopolsky, Snider, & Bar-Or, 2006; Tkachuk & Martin, 1999; You & Nicklas, 2008), suggesting constraint of sympathetic responses to stress that could plausibly contribute to reductions in clinical disorders such as hypertension, heart failure, oxidative stress, and suppression of immunity (Dishman et al., 2006).

Recent evidence has demonstrated the positive effects of physical activity or exercise on reducing chronic diseases such as cardiovascular disease, diabetes, cancer, obesity, osteoporosis, and fall-related injuries (Campbell & McTiernan, 2007; Friedenreich & Cust, 2008; Giada, Biffi, Agostoni, Anedda, Belardinelli, Carlon et al., 2008b; Hu et al., 2007; Kangas et al., 2008; Qi et al., 2008). The strongest evidence of these positive effects has been provided for colon cancer, breast cancer, diabetes, and cardiovascular diseases, with maximal magnitudes of risk reduction reported as 75% for breast cancer, 49% for cardiovascular and heart diseases, 35% for diabetes, and 22% for colorectal cancer (Kruk, 2007). The results of a number of prospective studies and clinical trials evaluating the associations between physical activity and diabetes risk have consistently shown that regular physical activity at one’s job and during one’s commute and leisure time diminishes the risk of type 2 diabetes by 15%–60%, and that lifestyle interventions, including counseling for physical activity, nutrition, and body weight, reduce the risk by 40%–60% among adults with impaired glucose tolerance, and by about 20% among general individuals (Qi et al., 2008). Moreover, lifestyle changes that increase physical activity have been demonstrated to significantly reduce the risk of development of type 2 diabetes in individuals with impaired glucose tolerance, and modest weight change and achievable physical activity goals have translated to significant risk reduction for type 2 diabetes (Hu et al., 2007; Hu, Rico-Sanz, Lakka, & Tuomilehto, 2006; Ryan, 2003). Thirty minutes per day of moderate- or high-level physical activity has been shown to be an effective and safe way to prevent type 2 diabetes in all populations (Hu et al., 2007). Exercise and physical activity represent essential components of weight loss and management in the treatment of obesity among adult and child populations (Annesi & Unruh, 2008; Butte, Puvau, Adolph, Vohra, & Zakeri, 2007; Carrel, Clark, Peterson, Nemeth, Sullivan, & Allen, 2005; Daley et al., 2006; Dishman et al., 2006; Halle et al., 2004; Kalra, Dube, Pu, Xu, Horvath, & Kalra, 1999; Kelly et al., 2007; Kelly, Wetzsteon, Kaiser, Steinberger, Bank, & Dengel, 2004; McMurray et al.,

2007; Nassis et al., 2005; Penedo & Dahn, 2005; Shaibi et al., 2006; M. Taylor, Mazzone, & Wrotniak, 2005), as well as in the prevention of age-related weight gain (Callaghan, 2004).

Several randomized clinical trials have shown that physical activity interventions modify biomarkers of cancer risk (Campbell & McTiernan, 2007; McTiernan et al., 2006) and result in small positive effects on health and well-being outcomes among individuals with cancer (Conn et al., 2006). Meta-analysis of 57 randomized clinical trials indicates that exercise interventions (including multimodal exercise and walking programs) provide reductions in cancer-related fatigue (Kangas et al., 2008). Other studies have demonstrated that exercise interventions are associated with a diminished decline in cognitive functioning in patients with Alzheimer's disease (Lautenschlager et al., 2008; Stevens & Killeen, 2006; Yu et al., 2006). Exercise interventions (including progressive and intensive treadmill training programs) have been demonstrated to improve movement initiation time, gait rhythm, mobility, and quality of life, as well as to reduce postural instability, fall risk, and fear of falling in patients with Parkinson's (Bergen et al., 2002; Cakit et al., 2007; Herman, Giladi, Gruendlinger, & Hausdorff, 2007). Therapeutic exercise, particularly with an element of strengthening, has been determined to be an efficacious treatment for hip osteoarthritis (Fransen, McConnell, & Bell, 2002; Hernández-Molina et al., 2008; Zhang et al., 2007), with beneficial treatment effects for diminished osteoarthritis-associated pain and self-reported physical function (Fransen et al., 2002). Numerous randomized clinical trials have confirmed the efficacy of exercise therapy (including strengthening, aerobic, and water-based exercise) for the treatment of osteoarthritis, with effect sizes of 0.32 for strengthening exercise (95% CI: 0.23, 0.42), 0.52 for aerobic exercise (95% CI: 0.34, 0.70), and 0.25 for water-based exercise (95% CI: 0.02, 0.47; Zhang et al., 2007).

There is considerable evidence that exercise therapies represent a necessary component of effective behavioral treatments that reduce self-reported pain in individuals with chronic pain, including pain associated with cancer, arthritis, and other musculoskeletal disorders (Conn et al., 2008; Dittrich, Günther, Franz, Burt-scher, Holzner, & Kopp, 2008; Hernández-Molina et al., 2008; K. D. Jones, Adams, Winters-Stone, & Burckhardt, 2006; Mannerkorpi, 2005; N. F. Taylor et al., 2007; Tkachuk & Martin, 1999), with the exception of migraine headache, for which the evidence remains limited by a relatively low number of clinical trials, in addition to the indiscriminate application of different techniques

(Busch & Gaul, 2008; Fernández-de-Las-Peñas, 2008). In contrast, there is strong evidence supporting aerobic exercise as a treatment prescription for persons with fibromyalgia (K. D. Jones et al., 2006; Mannerkorpi, 2005), with the greatest effect and lowest attrition occurring in lower-intensity exercise programs. In fact, exercise therapy has been declared an essential component of treatment for individuals with fibromyalgia, resulting in improved health and fitness and decreased reported symptoms (K. D. Jones et al., 2006; Mannerkorpi, 2005), as long as exercise remains limited to an appropriate intensity and is modified by the client as necessary and is symptom limited (K. D. Jones et al., 2006).

Effects of Exercise on Mental Health

Fitness levels and regular physical activity have been reported to be inversely related to depression and other mood disturbances (Lee & Russell, 2003; A. J. Morgan & Jorm, 2008; Pelham, Campagna, Ritvo, & Birnie, 1993; Ströhle et al., 2007), as well as enhanced psychological health and well-being (Callaghan, 2004; Lane & Terry, 2000). Exercise has been determined to be an effective method of enhancing mood (Berger & Motl, 2000; Lane & Terry, 2000), as well as regulating negative mood. In particular, it has been found to be an effective regulator of anger and depression (Lane & Terry, 2000). In this regard, a growing body of literature has demonstrated that that exercise (including exercise interventions) is both viable and cost effective yet vastly underutilized in the treatment and prevention of psychological and emotional disorders and disturbances (Annesi & Unruh, 2008; Babyak et al., 2000; Blumenthal et al., 1999, 2007; Callaghan, 2004; Chaput, Arguin, Gagnon, & Tremblay, 2008; Daley et al., 2006; Daley, Copeland, Wright, & Wales, 2005; Dishman et al., 2006; Dittrich et al., 2008; Doyne, Schambless, & Beutler, 1983; Dunn et al., 2002, 2005; Folkins & Sime, 1981; Giada et al., 2008a, 2008b; Johnsgard, 2004; Kruk, 2007; Lee & Russell, 2003; A. J. Morgan & Jorm, 2008; Needham & Crosnoe, 2005; North, McCullagh, & Tran, 1990; Penedo & Dahn, 2005; Petruzello, Landers, & Salazar, 1993; Piquart, Duberstein, & Lyness, 2007; Salmon, 2001; Sime, 1987; Skrinar, Unger, Hutchinson, & Faigenbaum, 1992; Ströhle et al., 2007; Tkachuk & Martin, 1999; van Dixhoorn, Duivenvoorden, Pool, & Verhage, 1990). Exercise has been associated with lower levels of mood disturbances, including stress and hostility, among adolescents and middle-aged and elderly adults (Annesi & Unruh, 2008; Blumenthal et al., 2007; Camacho, Roberts, Lazarus, Kaplan, & Cohen, 1991; Daley et al., 2006; Emery, Hauck, & Blumenthal, 1992; Lee & Russell, 2003; A. J. Morgan & Jorm, 2008;

Norris, Carroll, & Cochrane, 1992; North et al., 1990; Penedo & Dahn, 2005; Pinquart et al., 2007; Rajala, Uusimäki, Keinänen-Kiukkaanniemi, & Kivela, 1994; Ruuskanen & Parkatti, 1994; Ströhle et al., 2007; Weyerer, 1992). Exercise interventions have been shown to be comparable to psychopharmacologic medications (e.g., Zolof, an SSRI) for the treatment of major depressive disorder, both immediately following treatment and at 6-month follow-up (Babyak et al., 2000; Blumenthal et al., 1999, 2007).

In one recent study, 202 adults (153 women; 49 men) diagnosed with major depression were randomly assigned to either supervised exercise in a group setting, home-based exercise, antidepressant medication, or placebo pill for 16 weeks following completion of a structured clinical interview for depression and the Hamilton Depression Rating Scale (HAM-D; Blumenthal et al., 2007). Remission was defined as no longer meeting the criteria for major depressive disorder and a HAM-D score of <8 . Patients in the active treatment groups achieved higher remission rates than those receiving the placebo pill, such that patients who exercised achieved remission rates comparable to those of patients who received psychopharmacologic therapy (Blumenthal et al., 2007). However, the relatively high placebo response rates suggested that a considerable portion of the therapeutic response was determined by patient expectations, ongoing symptom monitoring, attention to the patient, and other nonspecific factors (Blumenthal et al., 2007). Importantly, long-term effects on mood have been noted for exercise, with lower relapse rates noted for individuals who continue to exercise habitually than for those who manage their depression through medication (Babyak et al., 2000; Blumenthal et al., 1999, 2007).

A meta-analysis of 57 controlled intervention studies revealed a medium effect size for physical exercise interventions, with weaker effects for studies that employed active control groups and studies of physically ill, cognitively impaired, and depressed patients (Pinquart et al., 2007). Another meta-analysis determined that exercise is associated with decreased depressive symptoms, with both immediate and longer-term effects; the effects were strongest for older individuals, along with persons with greater mood disturbance and decreased levels of physical fitness at the initiation of the interventions. No differences were noted between men and women (North et al., 1990). Emerging research has shown exercise to be effective in the maintenance of cognitive and mental functioning, and in delaying cognitive decline associated with dementia (Dishman et al., 2006; Stevens & Killeen, 2006; Yu et al., 2006).

Multiple flaws in design, particularly the assignment to experimental and control conditions, have been found in the studies that have failed to demonstrate appreciable effects of exercise on the outcomes of interest. Also, adherence has been noted to be highly problematic (Annesi & Unruh, 2008; Barnowski & Sallis, 1994; Busch & Gaul, 2008; Conn et al., 2006, 2008; Dishman, 1994; Emery et al., 1992; Fransen et al., 2002; Halle et al., 2004; Hernández-Molina et al., 2008; Hu et al., 2007; K.D. Jones et al., 2006; Kalra et al., 1999; Kangas et al., 2008; Kruk, 2007; Liddle, Gracey, & Baxter, 2007; Mannerkorpi, 2005; A.J. Morgan & Jorm, 2008; North et al., 1990; Penedo & Dahn, 2005; Pinquart et al., 2007; Ryan, 2003; Salmon, 2001; N.F. Taylor et al., 2007; Yu et al., 2006; Zhang et al., 2007), especially in a number of poorly designed or controlled studies. However, more potential benefit than risk has been conferred to exercise therapy (Annesi & Unruh, 2008; Babyak et al., 2000; Blumenthal et al., 1999, 2007; Daley et al., 2006; Dishman et al., 2006; Johnsgard, 2004; A.J. Morgan & Jorm, 2008; Penedo & Dahn, 2005; Pinquart et al., 2007; Ströhle et al., 2007).

Exercise that is rhythmic, noncompetitive, and predictable has been described as maximizing psychological benefits (Berger, 1994; Thayer, 2001; Thayer, Newman, & McClain, 1994). In this regard, a vast body of literature has demonstrated that moderate exercise is one of the most effective techniques for regulating mood (Annesi & Unruh, 2008; A.J. Morgan & Jorm, 2008; Thayer, 2001; Thayer et al., 1994). However, only one-third of the population reports exercising when moods are low (Thayer et al., 1994). Also, while a growing number of mental health practitioners have recognized the potency of exercise as a valuable adjunct to mental health therapy (Hays, 1995, 1996, 1999; Johnsgard, 2004; Sime, 2002; Steptoe & Cox, 1988; Steptoe, Kearsley, & Walters, 1993; Steptoe, Moses, Edwards, & Mathews, 1993), very few mental health providers indicate that they are comfortable using exercise as therapy or feel confident or comfortable engaging in exercise or walk/talk therapy (Callaghan, 2004; Hays, 1999; McEntee & Halgin, 1996).

Dose Response and Type of Exercise Effects on Mental Health

Both aerobic exercise (e.g., running, swimming) and anaerobic exercise (e.g., strength training) have demonstrated positive effects on mental health outcomes, with strong effects noted for strength training in reductions in anxiety, depression, and hostility (Berger & Owen,

1992; Folkins & Sime, 1981; Norris et al., 1992; Norvell & Belles, 1993; Salmon, 2001). Walking and running have been noted to be particularly beneficial for reducing depression in some populations, such as middle-aged and elderly adults (Blumenthal et al., 1999; Bosscher, 1993; Emery et al., 1992; King, Oman, Brassington, Bliwise, & Haskell, 1997; McMurdo & Rennie, 1993; O'Connor & Youngstedt, 1997; Penedo & Dahn, 2005; Pinquart et al., 2007). Although some types of exercise are believed to be more effective at improving mental health than others, personal preference and enjoyment of an activity may be more important in providing mental health benefits than the specific physical activity in which one engages (Rowlands, Eston, & Ingledew, 1997; Ruuskanen & Parkatti, 1994; Ryan, 2003; Sallis, Haskell, Fortmann, Vranizan, Taylor, & Solomon, 1986; Sallis, Alcaraz, McKenzie, Hovell, Koloday, & Nader, 1992; Saunders, Motl, Dowda, Dishman, & Pate, 2004; Saunders, et al., 1997; Strauss, Rodzilsky, Burack, & Colin, 2001; Ströhle et al., 2007; N.F. Taylor et al., 2007; van Duyn et al., 2007; Wankel, 1993).

A number of studies have suggested that moderate-intensity and high-intensity exercise produce comparable effects on mental health outcomes in the treatment of mild to moderate depressive disorder (Blumenthal et al., 1991, 1999, 2007; Doyne et al., 1983; Dunn et al., 2002, 2005; Martinsen, 1993; Singh, Stavrinou, Scarbek, Galambos, Liber, & Fiatarone Singh, 2005), and that low-intensity exercise is comparable to placebo (control) or standard care conditions. Very few studies have examined the effects of frequency or duration of exercise on mental health outcomes. One study determined that stronger effects (e.g., decreased depression) were associated with increased number of exercise sessions (North et al., 1990), whereas other research failed to determine such effects (Dunn et al., 2002, 2005). Other research did not find any differences between shorter (15 minutes) and longer (30 minutes) periods of exercise (Daley & Welch, 2004). Interestingly, enhanced well-being, decreased psychological distress, and diminished fatigue lasting up to 2 hours were noted for both short and longer periods of exercise (Daley & Welch, 2004).

THEORETICAL PARADIGMS

A number of physiological mechanisms have been postulated for the emotional and psychological benefits of exercise, including thermogenic effects, endorphin release, release of other neurotransmitters, and cognitive and social factors.

The Thermogenic Hypothesis

The thermogenic hypothesis stipulates that the elevation of core body temperature levels both during and immediately following moderate to intense exercise is associated with simultaneous diminished muscle tension (de Vries, Beckman, Huber, & Dieckmeir, 1968), which has been hypothesized to induce a calming effect. Exercise has been demonstrated to increase both heat and cold tolerance, with associated stabilization of mood (Dienstbier, 1991; Dienstbier, LaGuardia, & Wilcox, 1987). Thermogenic theory is supported by evidence that the physiological process of modulating core body temperature influences mood (Koltyn & Morgan, 1993). Core body temperature is believed to induce shifts in brain-wave laterality following intense exercise (Petruzzello et al., 1993), with both direct and indirect positive effects on mood (Robbins, 2000). The reductions in gamma motor activity have been determined to be associated with decreased muscle tension and state anxiety following exercise and passive heating (W.P. Morgan, 1988). The thermogenic hypothesis is supported by research focusing on reductions in anxiety but there is less evidence for the ameliorative effects of exercise on depression.

The Endorphin Theory

The endorphin theory focuses on the release of endogenous opiates following prolonged exercise, as occurs during endurance training, which is often described as a "runner's high" (Dietrich & McDaniel, 2004; Lobstein & Rasmussen, 1991). According to this theory, the increased serum and brain concentrations of endorphins caused by exercise are associated with changes in mental status, including analgesia, sedation, decreased anxiety, and an overall sense of well-being (Dietrich & McDaniel, 2004). Increased endorphin levels have been associated with decreased stress reactivity (McCubbin, Cheung, Montgomery, Bulbulian, & Wilson, 1992) and diminished pain sensitivity (Haier, Quaid, & Mills, 1981). Additional support for this theory has been provided by a small study that used positron emission tomography to examine the effects of running on the binding of opiate receptors in the brain (Boecker et al., 2008). The results showed that euphoria was significantly increased after running and was correlated with decreased opioid binding in the prefrontal/orbitofrontal cortices, anterior cingulate cortex, bilateral insula, parainsular cortex, and temporoparietal regions.

The Neurotransmitter Theory

Depression and depressed mood have been determined to be associated with perturbations in monoamines associated with the norepinephrine and serotonin systems (Charney, 1998; Heninger, Delgado, & Charney, 1996). The different classes of antidepressant drug (e.g., the monoamine reuptake inhibitors, the monoamine oxidase inhibitors, and the monoamine receptor antagonists) all have a common pharmacological effect: they raise the synaptic concentrations of noradrenaline and serotonin (Nutt, 2002). Central monoamine depletion studies have suggested that elevated synaptic monoamine levels, rather than downstream postsynaptic changes in receptor sensitivity, are responsible for the therapeutic effect of antidepressant drugs (Nutt, 2002). Exercise has been demonstrated to increase levels of norepinephrine and serotonin in the brain, in addition to increasing serotonin receptor sensitivity, thus promoting positive mood and acting as an antidepressant (Johnsgard, 2004). Finally, the decreased sympathetic and increased parasympathetic activity induced by exercise has been associated with improved emotional stability (Kubitz & Landers, 1993; Perna, Antoni, Kumar, Cruess, & Schneiderman, 1998).

Rebound Restorative High-Quality Sleep Theory

Sleep disturbances, including perturbations in the quality and quantity of sleep, have been associated with a plethora of mental and medical conditions (Aronen, Paavonen, Fjallberg, Soininen, & Torronen, 2000; Beebe et al., 2007; Benca, Obermeyer, Thisted, & Gillin, 1992; Carskadon, Plesch, & Millman, 1993; Chervin, Dillon, Bassetti, Ganoczy, & Pituch, 1997; Cohen, Ferrans, Vizigirda, Kunkle, & Colinger, 1996; Corkum, Moldofsky, Hogg-Johnson, Humphries, & Tannock, 1999; Corkum, Tannock, & Moldofsky, 1998; Dahl, 1996; Daniels et al., 2005; Darko, McCutchan, Kripke, Gillin, & Golshan, 1992; DeVincent, Gadow, Delosh, & Geller, 2007; Johnson, Chilcoat, & Breslau, 2000; Pilcher, Ginter, & Sadowsky, 1997). One study that randomly assigned elderly individuals (older than 60 years of age) with depression to high- and low-intensity progressive resistance training or standard care by a general practitioner revealed greater reductions in depression and improved quality of sleep in the high-intensity group than in the groups that received low-intensity training and standard care (Singh et al., 2005). While sleep quality improved in all groups, the greatest effects were noted for the high-intensity

group (Singh et al., 2005). Exercise has been shown to improve sleep onset, duration, and quality (King et al., 1997; O'Connor & Youngstedt, 1997), even in the face of elevated caffeine intake (Youngstedt, O'Connor, Crabbe, & Dishman, 2000). Insufficient sleep quantity and poor quality sleep have been demonstrated to promote negative mood disturbances (Dahl, 1996; Dinges et al., 1997), whereas adequate sleep quantity and quality have been shown to promote positive mood (King et al., 1997; Pilcher et al., 1997). Thus, exercise has been postulated to promote positive mood via the promotion of sleep quantity and quality.

Psychosocial Theories

The cognitive ("distraction") hypothesis stipulates that exercise provides a temporary timeout from everyday preoccupations and stressors (Bahrke & Morgan, 1978). The mastery hypothesis has suggested that exercise leads to a sense of mastery, with concomitant improved mood (Annesi & Unruh, 2008; Bandura, 1977; Simons, McGowan, Epstein, Kupfer, & Robertson, 1985). The mastery hypothesis is derived from research that has demonstrated that feelings of self-efficacy are associated with a profoundly positive impact on mood (Bandura, 1977, 1989). In this regard, exercise has been associated with increased self-mastery, self-efficacy, and self-esteem (Annesi & Unruh, 2008). Exercise has been described as a means to effectively regulate "social distance," such that the social interaction that occurs during certain forms of exercise (e.g., walking, running, or cycling) drives the pleasure derived from physical activity (Berger, 1984; Hays, 1994, 1999). In contrast, exercise has also been construed as providing much-needed solitude for individuals who find themselves overstimulated by excessively demanding social interactions (Berger, 1984; Hays, 1994, 1999). Hays (1999) has stipulated that mental health practitioners from a variety of theoretical orientations, including cognitive-behavioral, psychoanalytic, psychodynamic, systems, and feminism theories, and developmental, counseling, Eastern, and experiential perspectives, may maintain their theoretical perspective and practice methods while incorporating knowledge and skills from exercise and sport psychology, with the intent to include exercise psychotherapy in the scope of their respective practices (Hays, 1999).

Interaction Effects

The physiologic and psychosocial theories may have interaction effects. The biopsychosocial model reflects

interactions among biological (including physiological), psychological (including emotional), and social processes (Rejeski & Thompson, 1993). Elevation of core body temperature may increase the release, synthesis, or uptake of endorphins and/or monoamines, or neurotransmitters may act synergistically (Hamachek, 1987; W.P. Morgan, 1988; Perna et al., 1998). Regarding interactive psychosocial effects, exercise has been associated with increased hardiness and feelings of self-worth, which were mediated by increased social support (Oman & Haskel, 1993). Attenuated sympathetic nervous system activation has also been related to increased hardiness among certain populations (Dienstbier, 1991).

PRACTITIONERS AND EXERCISE

Given the direct and indirect benefits of exercise on mental and physical health, what percentage of health care providers report regularly exercising, or regularly recommending exercise to their patients or clients? Several studies reveal that 50%–75% of mental health care providers report engaging in regular physical exercise (Barrow, English, & Pinkerton, 1987; Burks & Keeley, 1989; Coster & Schwebel, 1997; Hays, 1995, 1996; Lehofer, Klebel, Gersdorf, & Zapotoczke, 1992; Royak-Schaler & Feldman, 1984). However, the majority of therapists indicate that they do not consistently recommend exercise to their clients (Barrow et al., 1987; Burks & Keeley, 1989; Callaghan, 2004). Along with other health care providers, such as physicians, certified nurse midwives, and physician assistants (Pender, Sallis, Long, & Calfas, 1994), mental health care providers are more likely to report that they would recommend exercise if they themselves exercised (Royak-Schaler & Feldman, 1984). Therefore, most exercise recommendations tend to come from practitioners whose beliefs and practices are largely self-informed, so that practitioners benefiting from exercise are most likely to encourage their patients to engage in physical activity (McEntee & Halgin, 1996). However, when a practitioner prescribes or recommends treatment (e.g., such as exercise) without the provision of either supervision or adequate guidance, patients tend not to follow through, or they cannot maintain a regular program of exercise over the long term (Goldstein et al., 1999; Pinquart et al., 2007). Exercise prescriptions have been demonstrated to require intensive and prolonged interventions in order to produce appreciable continuity in physical activity among middle-aged and elderly adults and require programs tailored specifically to the unique history and personal

life experiences of each individual (Marcus, Bock, Pinto, Forsyth, Roberts, & Traficante, 1998; Pinquart et al., 2007). While other therapies require a certain level of adherence to achieve the desired (e.g., curative) outcomes, adherence has been noted to be highly problematic for exercise interventions (Pinquart et al., 2007).

The percentage of practitioners who utilize exercise psychotherapy with their clients is largely undetermined. One study that surveyed mental health practitioners revealed that the majority of practitioners do not exercise or utilize exercise psychotherapy with their clients (Hays, 1996). Very few mental health providers indicate that they are comfortable using exercise as therapy or feel confident or comfortable engaging in exercise or walk/talk therapy (Callaghan, 2004; Hays, 1996, 1999; McEntee & Halgin, 1996).

MEASUREMENT

Several scales have been validated for the assessment of the important domains of emotional functioning among adult populations, including the Profile of Mood States (POMS) (McNair, Lorr, & Droppleman, 1971, 1992); the Beck Depression Inventory–II (BDI-2) (Beck, Steer, & Brown, 1996) for dysphoria; the State-Trait Anxiety Inventory (STAI) (Spielberger, Edwards, Lushene, Montuori, & Plazek, 1973; Spielberger, Gorsuch, & Lushene, 1970; Spielberger, Gorsuch, Lushene, Vagg, & Jacobs, 1970) for anxiety; the Brief COPE, a brief measure of coping assessing effective and ineffective coping, also with demonstrated adequate reliability and validity (Carver, 1997); the Attributional Style Questionnaire (ASQ) (Schulman, Castellon, & Seligman, 1989) for optimism and forward thinking; and the Goals Scale (Babyak, Snyder, & Yoshinobu, 1993) for hope. Sleep (including onset, duration, and quality) represents an important component of mood. The Sleep Assessment Questionnaire (SAQ) has been used to determine sleep disturbances (Mansfield, Cesta, Sammut, & Moldofsky, 2000), and the Epworth Sleepiness Scale has been used to measure daytime fatigue associated with sleep deprivation or non-restorative sleep (Johns, 1991).

The following measures have been validated for the assessment of emotional functioning among child and adolescent populations: the Child Depression Inventory (CDI) (Kovacs & Beck, 1977) for dysphoria; the KIDCOPE, a coping checklist for children, with demonstrated reliability and validity (Spirito, Stark, & Williams, 1988); the State-Trait Anxiety Inventory for Children (STAI-C) (Spielberger et al., 1973) for anxiety; the Children's Attributional Style Questionnaire (C-ASQ) (Selig-

man Kaslow, Alloy, Peterson, Tanenbaum, & Abramson, 1984) for optimism and forward thinking; and the Goals Scale (Snyder et al., 1997) for hope. All these measures are age appropriate, have been used with and/or are relevant to child populations, and have published norms. Sleep (including onset, duration, and quality) may be assessed with daily sleep logs, in which information regarding about sleep schedule (bedtime, waking time), sleep quality (night waking, sleep latency), and tiredness during the day is recorded (Franck et al., 1999; Gruber, Sadeh, & Raviv, 2000); the Children's Sleep Behavior Scale, which assesses children's sleep-related behaviors during the previous 6-month period via parent report (Fisher & McGuire, 1990) and covers a wide range of sleep behaviors, including sleep onset, restless sleep, night wakings, behaviors that occur while the child is sleeping (e.g., smiling, bruxism), nightmares, and morning waking (Fisher & McGuire, 1990; Fisher, Pauley, & McGuire, 1989); the Children's Sleep Habits Questionnaire (SHQ), which assesses domains of bedtime behavior, sleep behaviors such as parasomnias, other night wakings, morning waking, and daytime sleepiness via parent report; and the Child Sleep Questionnaire-Parent Version (CSQ-P), which assesses sleep problems and sleep-related concerns for children ages 5–12 years old (Blader, Koplewicz, Abikoff, & Foley, 1997).

For both adult and child populations, physical activity and related key domains have been assessed with the 3-Day Physical Activity Recall (3DPAR) (Saunders et al., 1997; Ward, Saunders, & Pate, 2007); the Self-Efficacy for Physical Activity instrument (SE-PA) (Saunders et al., 1997; Ward et al., 2007); the Enjoyment of Physical Activity instrument (E-PE) (Ward et al., 2007); the Social Support for Physical Activity instrument (SS-PE) (Saunders et al., 1997). Perceived accessibility to exercise equipment (Motl, Dishman, Saunders, Dowda, & Pate, 2007; Motl et al., 2005) and perceived neighborhood safety (Motl et al., 2005, 2007) have also been assessed. Clients and patients can rate the effectiveness of exercise as a strategy to reduce anger, confusion, depression, fatigue, and tension and increase vigor by using a questionnaire developed by Thayer et al. (1994). The Exercise Induced Feeling Inventory is a 12-item, four-dimensional (tranquility, revitalization, positive engagement, and physical exhaustion) scale used to measure affective response to acute exercise (Gauvin & Rejeski, 1993).

During exercise, the therapist teaches the client how to measure intensity using measures of perceived effort (or exertion), such as the Rating of Perceived Effort (Exertion) (RPE) by Borg, with modified levels of 1–10 for

levels of perceived exertion or fatigue (Borg, 1985; Borg, Ljungren, & Ceci, 1985). Clients with lower levels of conditioning should initially maintain comfortable levels of intensity (e.g., no higher than a 3) in order to build a sense of efficacy, especially during the first weeks of exercise. Another very effective and easily adaptable measure of intensity is the “talk test,” that is, whether or not one can maintain a conversation while exercising (Berger, 1984; Persinger, Foster, Gibson, Fater, & Porcari, 2004; Sime & Sanstead, 1987). Clients should be able to speak in complete sentences while exercising with the therapist and should not need to pause between words in order to complete a sentence. However, exercise should be sufficient enough for the client to break a light sweat.

APPROPRIATE POPULATIONS FOR EXERCISE PSYCHOTHERAPY

Research regarding exercise interventions demonstrates that patients with mild to moderate depression may benefit from exercise psychotherapy, either independently or as an adjunctive treatment to psychopharmacologic treatment (Annesi & Unruh, 2008; Babyak et al., 2000; Blumenthal et al., 1999, 2007; Daley et al., 2006; Dishman et al., 2006; Dunn et al., 2002, 2005; Johnsgard, 2004; A.J. Morgan & Jorm, 2008; North et al., 1990; Penedo & Dahn, 2005; Piquart et al., 2007; Salmon, 2001; Tkachuk & Martin, 1999). While the evidence provides growing support for the benefits of exercise in this population, many patients demonstrate difficulties initiating physical activity due to the anergia that so often accompanies (and even characterizes) depressive symptomatology. In this regard, patients may be more amenable to walk/talk therapy during the course of the therapy session than attempting to initiate exercise independently. Such an initiation may provide the impetus for the patient to engage in additional physical activity during interim time periods between sessions. Exercise psychotherapy may have particular benefits among patients with anxiety disorders (Johnsgard, 2004; Petruzello et al., 1993; Salmon, 2001; Shearer et al., 2001; Tkachuk & Martin, 1999).

Several specific populations have been identified as potentially benefiting from exercise therapies: adolescents, the elderly, persons with disabilities, and individuals who are overweight or obese. Aerobic exercise (e.g., running) has been determined to be an efficacious treatment for adolescents, including those with psychiatric disturbances (S. Brown, Welsh, Labbe, Gitulli, & Kulkarni, 1992; Daley et al., 2006; Lohman et al., 2006;

Norris et al., 1992; Ströhle et al., 2007), with reductions in depression, anxiety, fatigue, and hostility noted. A number of studies with middle-aged and elderly adults have described the benefits of exercise interventions in reducing depression (Blumenthal et al., 1999, 2007; Dunn et al., 2002, 2005; King et al., 1997; Lee & Russell, 2003; North et al., 1990; O'Connor & Youngstedt, 1997; Piquart et al., 2007). Exercise has been shown to improve psychological well-being among persons with physical disabilities (D. Brown, 1993; Graham et al., 2008; Shephard, 1991). One study determined that decreased anxiety is associated with hand-crank exercise among persons who use a wheelchair for mobility (S. Brown et al., 1992). Another recent (albeit small) study suggested that a seated exercise program facilitated active management of disability-related mood disturbances (Graham et al., 2008). Exercise interventions have been determined to be efficacious in facilitating weight loss in overweight and obese individuals (Annesi & Unruh, 2008; Butte et al., 2007; Carrel et al., 2005; Cooper, Nemet, & Galassetti, 2004; Daley et al., 2006; Halle et al., 2004; Kelly et al., 2004, 2007; Lohman et al., 2006; McMurray et al., 2007; Nassis et al., 2005; Shaibi et al., 2006; M. Taylor et al., 2005), with noted improvements in both psychological and physical health parameters.

DISADVANTAGES OF EXERCISE PSYCHOTHERAPY

Exercise prescriptions outside exercise psychotherapy may be counterproductive, even contraindicated, for some clients. A patient who fails to achieve success from an exercise prescription may experience guilt, which may exacerbate rather than alleviate mood disturbances (Hays, 1999; Sime, 2002; Thayer, 2001). Other contraindications may include medical problems or personal preferences based upon age or prior negative experiences (Hays, 1999; Sime, 2002; Thayer, 2001). While the active process of exercise therapy has therapeutic potential and value, a certain degree of risk to the client is associated with the intensity and type of exercise (e.g., aerobic, anaerobic, or leisure activity) chosen (Hays, 1999; Johnsgard, 2004; Sime, 2002; Thayer, 2001). However, other therapies, including pharmacologic and psychotherapeutic therapies, offer therapeutic benefits and risks of side effects as well.

Similar problems with adherence and recidivism exist with all therapies. Exercise necessitates a certain degree of accommodation and potential discomfort, so it is no surprise that 20%–50% of healthy as well as

clinical populations have shown decreased adherence at 6-month follow-up visits (Dishman, 1991, 1994; Piquart et al., 2007). However, both psychotherapy and drug therapies have been noted to be compromised by client non-adherence and side effects (Blumenthal et al., 1999, 2007; Martinsen & Stanghelle, 1997; Piquart et al., 2007). Explaining to clients and patients both the immediate and longer-term positive effects of exercise on mood may improve adherence and efficacy of treatment (Daley & Welch, 2004; van Dixhoorn et al., 1990).

Although exercise has been determined to be an effective method of enhancing mood (Berger & Motl, 2000), excessive training has been associated with negative mood (Raglin & Morgan, 1994). The therapeutic value or nature of exercise can be compromised when exercise is overused or is used as a substitute for addressing life stressors (Hays, 1999; Raglin & Morgan, 1994; Sachs & Pargman, 1984; Thayer, 2001). Indicators of exercise overuse or overtraining include irritability or anger, fatigue, depressed mood, and a reduced sense of well-being (A.J. Morgan & Jorm, 2008; W.P. Morgan, 1988).

Disadvantages of exercise psychotherapy as a modality for treatment are therapists' difficulties maintaining interpersonal boundaries, as well as potential liability and malpractice issues (Hays, 1999; Johnsgard, 2004; Sime, 2002). Therapists need to carefully attend to ethical practices regarding the maintenance of interpersonal boundaries (Hays, 1999; Johnsgard, 2004; Sime, 2002).

PRACTICAL APPLICATIONS

Several authors have described methods for incorporating exercise prescriptions into therapy, with the goal of facilitating the initiation and maintenance of physical activity (Hays, 1999, 2002; Johnsgard, 2004; Leith, 1998; Sime, 2002; Thayer, 2001). Through this process, the mental health practitioner (1) helps the client choose the type of exercise that is most enjoyable (e.g., walking or biking, gardening, playing sports with friends or children), as enjoyment has been determined to be a key component of the maintenance of physical activity patterns (Hays, 1999; Johnsgard, 2004; Sime, 2002); (2) helps the client choose the time of day to exercise (morning, lunch, evening) when he or she is most likely to engage in the activity; (3) suggests that the client purchase an item of clothing appropriate for the activity (e.g., walking/running shoes, performance T-shirt or shorts, socks) and begin to read fitness or

sport-specific magazines; (4) suggests that the client put his or her athletic clothes out the night before; (5) suggests that the client convince him- or herself to exercise only for 5–10 minutes then quit, as a means to get started (although the intent is to continue for the selected duration); helps the client set challenging yet reasonable goals (e.g., 10–15 minutes, 3–4 times per week); and helps the client view exercise as part of overall health, like brushing his or her teeth and getting enough sleep; (6) helps the client identify and resolve potential barriers to exercise, such as not wanting to exercise alone, feeling embarrassed in front of other people, and feeling too tired after driving home from work; and (7) suggests that the client practice the “80/20 rule” (80% healthy choices and 20% self-forgiveness) as a means of dealing with setbacks.

The following practice guidelines are suggested for incorporating exercise and/or exercise psychotherapy into treatment. The therapist may elect to have the client utilize *Move Your Body, Move Your Mood*, an excellent workbook by Hays (2002).

- (1) Assess the client's current exercise, including all physical activities and habits that incorporate both work and leisure settings (Hays, 1999; Sime, 2002). Explore past experiences with exercise, both positive and negative, in order to identify positive opportunities for exercise psychotherapy (Hays, 1999; Sime, 2002).
- (2) Obtain medical clearance as well as permission to speak with health care professionals regarding the client's physical readiness to engage in moderate exercise during therapy (Hays, 1999; Johnsgard, 2004; Sime, 2002). Establish and maintain communication with medical professionals caring for clients regarding progress and concerns (Hays, 1999; Johnsgard, 2004; Sime, 2002).
- (3) Assess client ability and motivation to engage in exercise psychotherapy, as not all persons demonstrate willingness to utilize such an approach (Hays, 1999; Johnsgard, 2004; Sime, 2002). However, it is important not to preclude persons with serious medical illnesses or disabilities, given the strong empirical evidence demonstrating positive outcomes among medical subpopulations, including individuals with multiple sclerosis, osteoarthritis of the knee, chronic low back pain, coronary heart disease, chronic heart failure, and chronic obstructive pulmonary disease (Borg et al., 1985; Conn et al., 2008; Focht, Brawley, Rejeski, & Ambrosius, 2004; Fransen et al., 2002; Giada et al., 2008a, 2008b; Hernández-Molina et al., 2008; Lett, Davidson, & Blumenthal, 2005; Liddle et al., 2007; Sniehotta, Scholz, Schwarzer, Fuhrmann, Kiwus, & Voller, 2005; N.F. Taylor et al., 2007; Tkachuk & Martin, 1999).
- (4) Suggest proper clothing prior to engaging in exercise psychotherapy, such as comfortable walking shoes for walking, and performance apparel. Sedentary individuals may select clothing (e.g., cotton or non-performance polyester) that actually increases discomfort during exercise or may not be aware that sport-specific shoes exist. Many discount retail stores carry affordable performance apparel clothing lines.
- (5) Ask the client to rate her or his mood, as well as levels of energy and tension during the session (see survey of measurements, above).
- (6) Suggest a walk during the therapy session, either in office building hallways (with limited foot traffic) or on the sidewalk outside the building, if weather permits (Hays, 1999; Sime, 2002). The therapist may wish to limit the initial walk to 10–20 minutes or less, depending on the physical condition of client, as well as the attractiveness and distractions of the setting (Hays, 1999; Sime, 2002).
- (7) Note if the client opens up and becomes more interactive during the walk (Hays, 1999; Sime, 2002). Conversely, if the client appears intimidated by or otherwise uncomfortable with the idea of leaving, return immediately to the office setting (Hays, 1999; Sime, 2002).
- (8) Describe to the client the benefits of walk/talk therapy before, then again during and after, the walk (Hays, 1999; Sime, 2002). Ask the client to assess mood, energy, and tension after 5 minutes of walking. Using the ratings of mood, energy, and tension provided by the client, emphasize the invigorating aspects of exercise, as well as the refreshing aspects of recovery provided by exercise (Hays, 1999; Sime, 2002). The provision of a brief rationale regarding the potential benefits of exercise, including the aesthetic and kinesthetic experiences associated with movement, and its synergistic effects may benefit the client as well as promote between-session physical activity (Hays, 1999; Sime, 2002).
- (9) During the walk, assess the client's level of intensity (e.g., using the talk test or Borg scale, or by checking to see if he or she has broken a light sweat), and discuss the desired duration of exercise. The therapist should attend carefully to the client, who should be able to speak in complete sentences while exercising with the therapist and should not need to pause between words in order to complete

a sentence. However, exercise should be sufficient enough for the client to break a light sweat.

- (10) Assess overall progress with mood and sleep inventories (e.g., the Beck Depression Inventory-II, State-Trait Anxiety Inventory, or Profile of Mood States), on a weekly, monthly, quarterly, or other predetermined basis (Hays, 1999; Johnsgard, 2004; Sime, 2002).
- (11) Adhere to strict ethical practices, such as establishing and maintaining clear ethical boundaries (Hays, 1999; Sime, 2002). Some clients may misinterpret the informal quality of exercise as connoting a more social and less professional relationship (Hays, 1999; Sime, 2002). The therapist is responsible for facilitating exercise during the session yet maintaining strict professional and ethical boundaries, while highlighting the benefits of physical activity to the client (Hays, 1999; Sime, 1987, 2002). The mental health practitioner should include in the discussion the modality of exercise psychotherapy (including purpose, methods, and treatment settings) in the scope of practice and for presentation to clients, as well as for professional licensing and ethics boards, in order to avert any potential problems with a disgruntled client or concerned community member (Hays, 1999; Sime, 2002).

CONCLUSION

Given the strong empirical base for exercise therapies' ability to improve both physical and psychological health outcomes among a variety of populations, it stands to reason that exercise psychotherapy represents an efficacious treatment modality. However, given the dearth of empirical research, future studies are warranted to evaluate the effectiveness and efficacy of this relatively new treatment modality.

Meditation and Neuroscience: From Basic Research to Clinical Practice

Claire Braboszcz
Stéphanie Hahusseau
Arnaud Delorme

Meditation has been extensively practiced in many civilizations for thousands of years as a means of cultivating a state of well-being and for religious purposes. It has now started to be studied in terms of its influence on the brain and body and used in clinical settings. This chapter will first review meditation effects at the physiological, attentional, and affective levels and the scientific paradigms used to study these effects. A clinical application on emotion regulation will then be presented.

Spiritual practices that aim at transcending the common state of consciousness can be found in human societies all over the world down to shamanic practices in the Paleolithic (Walter & Neumann Fridman, 2004; Winkelman, 2000). Formal references to meditation can be found in ancient texts as early as the third century BCE in the Buddhist writings of the Abhidharma (Cox, 2004). Today, “meditation” is used as a generic term to refer to a wide range of practices for self-regulation of emotion and attention (Gunaratana, 2002) and is considered an inherently experiential practice present in most religious or philosophical traditions. Meditation generally involves focusing one’s attention on a partic-

ular physical or mental object. When mind wandering occurs, practitioners are instructed to bring their attention back to the meditative task. Meditation practices often involve altered states of consciousness although these typically only arise during intensive practices of several hours a day. Meditation practitioners often perform daily meditation for a period of time ranging from 15 minutes to several hours, with the goal of getting insight into the nature of their minds and the universe or reaching a state beyond the materialistic world and connecting with the infinite (or a divinity, depending on the meditation tradition).

Based on the assumption that different conscious states are accompanied by different neurophysiological states, a neuroscientific approach to meditation focuses on altered sensory, cognitive, and self-awareness experiences. Meditation-induced neurophysiological changes may be of two kinds. Changes that occur during meditation practice are referred as state changes. Changes which build up over months or years and persist even when the mind is not actively engaged in meditation are referred to as trait changes (Cahn & Polich, 2006). On one hand, the study of meditation states

is especially relevant for consciousness research as a means of exploring the effect of meditation itself on the brain. On the other hand, the study of meditation traits is more particularly adapted to the study of meditation's beneficial effects on health and general well-being in association with potential clinical applications.

There are a large number of distinct meditative practices, but given that self-regulation of attention is a major component that is common among all of them, it is possible to classify meditative style on a continuum, depending on how attentional processes are directed (Cahn & Polich, 2006). Lutz, Slagter, Dunne, and Davidson (2008) proposed a theoretical framework in which meditation practices are categorized in two main groups. Concentrative—or focused attention—techniques involve continuous sustained attention on a selected object: the object of focus may be breath or body sensations, a subvocal repeated sound or word (mantra), or an imagined mental image. Focused attention meditation requires the narrowing of awareness so that the mind only contains the object of focus. On the other hand, mindfulness meditation practices, also called open-monitoring or insight meditation, involve the expanding of awareness with no explicit focus (except awareness itself). In mindfulness, practitioners are instructed to allow any thought, feeling, or sensation to arise in consciousness while maintaining a nonreactive awareness to what is being experienced. Mindfulness may be described as sustained awareness aimed at nonreactive and nonattached mental observation, without cognitive or emotional interpretation of the unfolding moment-to-moment experience (Cahn & Polich, 2006; Gunaratana, 2002; Kabat-Zinn, 2003; Lutz, Slagter, et al., 2008).

DIFFERENT TYPES OF MEDITATION

Meditation traditions exist all over the world. A lengthy and exhaustive review would be necessary to attempt to describe each and every one of them, so this chapter will focus on only a few of them, mostly from Asian traditions, since these are the traditions that have been studied the most by Western scientists.

Soto Zen is a tradition based on mindfulness and open awareness. One practices it while sitting, usually facing a wall with open eyes. Practitioners are instructed to observe their thoughts and emotions arising in their minds and not to cling to them or engage in narrative thinking but simply let these thoughts or emotions go and remain purely aware of sitting. Every time practitioners realize that the mind has started to wander (i.e., they identified with a thought), they have to bring their

attention back to the present moment. This practice is also called *Shikantaza*, a Japanese term that means “nothing but precisely sitting.”

In *Rinzai Zen*, the other major form of Zen practice, practitioners are instructed to concentrate on koans. Koans are riddles that cannot be solved with knowledge or thinking. “What is the sound of one hand clapping?” is a popular Zen koan. Zen students are given a koan by a Zen teacher, depending on their level of development in the practice and their personality. They are then instructed to meditate on it until they can solve it. They regularly present their solution to their teacher and, if successful, are given a new koan. Koans are ways to help meditators get out of the thought-based state of ordinary consciousness and access pure awareness of the present moment.

Vipassana meditation is another meditation technique that is now widespread in the West. In *Vipassana*, practitioners begin by observing their breath around the area of the nostrils to help the mind develop sustained, focused attention. Every time the mind wanders, they have to bring it back to the sensation of breathing. As they do so, attention gets sharper and sharper. Then practitioners have to mentally scan sequentially and meticulously each part of the body and feel the sensation in each of these body parts. They continuously keep their attention moving down from head to toes and then up in the reverse direction. At first, they find it hard to experience sensation in each and every part of the body, but with practice, they progressively come to feel sensations in more parts of their bodies. Participants are only instructed to keep their attention moving and observe, objectively and with equanimity, the sensations that they are experiencing. Practitioners should try to avoid developing feelings of aversion or cravings for specific sensations, as this is believed to disturb both body and mind. *Vipassana* is a good example of a meditation practice in which focused attention and open monitoring are both incorporated.

Mantra or prayer meditation might be the most popular type of meditation worldwide and is present in Tibetan Buddhism, Sufism, Hinduism, and many other traditions. It became widespread in the West in the 1960s with the development of transcendental meditation (TM). A mantra is a religious or mystical sound, word, or poem that can be either recited aloud or subvocally. For instance, Hare Krishna practitioners are instructed to repeat the 16-word Hare Krishna mantra, “Hare Krishna Hare Krishna, Krishna Krishna Hare Hare, Hare Rama Hare Rama, Rama Rama Hare Hare,” 1,728 times a day, keeping the correct count with the help of

prayer beads. The particular body vibration that a mantra induces is believed to calm and focus the mind and body without the need for intense concentrative efforts. When meditators repeat the mantra, they are instructed to focus their full attention on the recitation, and also sometimes on its meaning if it has one. Some practices involve mantra repetition with awareness of the breath (and others without breath awareness). As with other types of meditation, when meditators experience mind-wandering episodes, they are simply instructed to bring their attention back to the mantra.

Mantra meditation is in many ways similar to slow reading or chanting of sacred texts while one absorbs their meaning. These practices are present in all religions and spiritual traditions. Texts involved may be sutras in Buddhism (discourse from the Buddha). Christian practices, for instance, involve recitation of a prayer phrase or the study of Scripture, which involves the slow reading of the Bible as the reader considers the meaning of each verse, and is practiced by monks of various orders. Although these practices are usually not specifically referred to as meditation, they involve focused attention and going beyond dialectic thinking, two traits they share with meditation.

Other forms of meditation may involve generating and focusing on feelings of loving-kindness or compassion toward all living beings (one of many Tibetan Buddhism practices). Mental visualization and careful examination of sacred objects is another common meditation practice in Tibetan Buddhism. Different practices can also be done while one is moving. In the case of walking meditation, one has to walk slowly, keeping breath coordinated with each step, and remain aware of every body sensation and movement. While working or doing simple tasks, one may simply be present and focused on the action being done now, that is, giving the present moment one's undivided attention, without thinking about past or future events. Walking and work meditation are an important part of Zen practice. Yoga is also a form of meditation in movement. It combines specific physical postures, breath patterns, and body awareness.

In most meditation traditions, daily practice is supplemented by retreats that involve intensive practice. These retreats are often held in complete silence. They can last from a few days to several months or even years. In the Tibetan meditation tradition, for instance, it is not uncommon to see dedicated practitioners engage in monastic life spending several years of their lives in complete silent isolation.

Finally, practices have been adapted for clinical use based on traditional forms of meditation. An example

is Jon Kabat-Zinn's mindfulness-based stress reduction program (Kabat-Zinn et al., 1992). This program involves a daily meditation practice and is usually taught in 2-hour weekly classes over a period of 8 weeks, including a full day of meditation.

HISTORY OF THE SCIENTIFIC STUDY OF MEDITATION

Meditation has been the subject of scientific research for about the past 40 years but only started to gain popularity in the late 1990s (Figure 27.1). The neuroscientific study of meditation has involved both fundamental and clinical research and aims at understanding how mental training affects the brain, the body, and overall health. In fundamental research, experience-induced changes in brain activity and anatomy, that is neuroplasticity, are a major focus of study (Bourgeois, 2005; Draganski, Gaser, Busch, Schuierer, Bogdahn, & May, 2004). Interestingly, recent results suggest that meditation, which is a purely mental activity, may also induce brain plasticity (Lutz, Greischar, Rawlings, Ricard, & Davidson, 2004). As it often triggers altered states of consciousness, meditation also holds an important place in the experimental framework of consciousness research (Lutz, Dunne, & Davidson, 2007; Thompson, 2006; Varela, Thompson, & Rosch, 1999). Both of these fields have benefited from the development of brain-imaging techniques (fMRI, PET, EEG, MEG) and progress in signal analysis (Friston, 2002; Lachaux, Rodriguez, Martinerie, & Varela, 1999; Makeig, Debener, Onton, & Delorme, 2004). These technological improvements allow for a better characterization of dynamical interactions in the brain and thus enable scientists to study problems that have long been relegated to the realm of philosophy, such as the question of consciousness. These recent developments, together with the development of medical practices incorporating meditation in therapeutic protocols—and thus the need to validate meditation's impact on the brain and body—account for the recent popularity of meditation studies in neuroscience research.

Scientific interest in meditation also reflects a recent shift in cognitive science toward viewing the integration of consciousness and first-person experience as a valuable object of scientific investigation. At the end of the 19th century, the importance of subjectivity and introspection were emphasized both in philosophy by Husserl (1936/1970) and in the scientific study of mental phenomena by William James (1890/1983). However, during the following decades, science attempted

Figure 27.1 Search results for the term “meditation” from PubMed, 1990–2007.

to reduce cognition and all mental phenomena to their observable consequences in the world. In the first part of the 20th century, behaviorists praised the study of the mind in examining behavioral performances and electrophysiological responses. Behaviorism led to a complete rejection of subjectivity and private experience, which were judged to be outside of the field of science. The development of cybernetics around 1940–1950 and the subsequent birth of cognitive science led scientists to regard the brain as an information-processing unit, and the architecture of the first computers was used as a model for the brain. Even though the work of Gestalt psychologists (Koffka & Schoen, 1955) and phenomenological philosophers such as Merleau-Ponty (1995) attempted to develop more subjective approaches to the mind, the reductionist approach to cognition has had a lasting influence on cognitive science. In the last two decades, the development of embodied and situated approaches to the mind has encouraged reconsideration of the body’s role as well as first-person experience in cognition. These approaches view cognition as arising from the coupled interactions of the brain, body, and environment (Damasio, 1994; Varela et al., 1991). This shift has been accompanied by the renewed use of subjective data in experimental protocols (Jack & Roepstorff, 2003; Varela & Shear, 1999). Coming from the embodied cognition perspective, which sees first-person experience as critical to a complete understanding of the mind, Varela developed the neurophenomenology approach, which combines

first-person report of subjective experience with experimental study of brain activity (Lutz et al., 2007; Thompson, 2006).

The neurophenomenology approach to meditation has been successfully applied in experimental studies of visual perception (Lutz, Lachaux, Martinerie, & Varela, 2002), in which subjects were extensively trained to report their subjective experience during a psychophysical visual task. For meditation to be integrated into experimental studies, neurophenomenology needs precise and reliable subjective descriptions of the mind during the meditative state. The neurophenomenology approach to meditation was adapted from Buddhist meditative psychology concepts (Lutz et al., 2004; Raffone et al., 2007; Varela et al., 1991). Buddhist meditative traditions, like many others, are based on mental training of capacities for sustained, attentive awareness of the moment-to-moment flow of experience, a practice that is supposed to allow the practitioner to develop deep insight into the nature and functioning of the mind and consciousness (Dreyfus & Thompson, 2006; Gunaratana, 2002). The basis of Buddhist meditative psychology is directly based on reports from expert meditators and is supposed to be empirically testable. While still in its infancy, neurophenomenology will certainly help us understand consciousness and bridge the gap between brain neural dynamics and subjective human experience (Rudrauf, Lutz, Cosmelli, Lachaux, & Le Van Quyen, 2003; Thompson, 2006; Varela et al., 1991).

MEDITATION AND THE PERIPHERAL NERVOUS SYSTEM

Since meditation is often considered to be a relaxation technique, it is reasonable to assume that meditation practice affects the functioning of the body. The mechanisms underlying the effect of meditation on the body are not yet understood, and as for cognitive and brain activity correlates of meditation, we currently lack formal evaluation procedures for the diverse meditation types and methodologies being used (Cahn & Polich, 2006). We will thus only provide a brief overview of interesting research directions.

Body Representation

Meditation induces long-lasting changes to one's body perception that can be observed both at low-level cortical representations and at higher-level representation associated with the sense of self (Cahn & Polich, 2006). Meditation-induced changes in cortical areas devoted to process inputs from the body are reported by Lazar et al. (2005) and could account for increased awareness of the sensory field. Lazar et al.'s study shows that regular practice of open-monitoring meditation—which focuses on both internal and external sensations—increases the thickness of the cortex in somatosensory areas of the brain. This increase in cortex thickness was positively correlated with meditation experience, so we may hypothesize that it functionally corresponds to an increase in body awareness. Testing this hypothesis, Khalsa, Rudrauf, Damasio, Davidson, Lutz, and Tranel (2008) had long-term meditators in both active (yoga) and sitting forms of meditation and non-meditators perform a heartbeat detection task in which participants had to tell whether or not short sounds were displayed synchronously to their own heartbeats (they had to try to feel their heartbeats without using their finger on peripheral arteries). He found that the meditators did not perform any better than the non-meditators. This suggests that changes in meditators' body representation are not functionally correlated with better perception of physiological sensation. However, in this study, meditators systematically rated their experience of interoceptive perception higher than did control subjects. Collection of their subjective experiences also revealed that they found the heartbeat-counting task to be easier than non-meditators did. Lazar et al.'s results might then directly index improved body awareness without improved body representation.

Meditation practice also induces changes in one's representation of the self. An fMRI study by Farb et al. (2007) showed a decreased coupling between the insular cortex, which is involved in the perception of pain and internal body responses, and the medial prefrontal cortex (mPFC), which is involved in higher-level cognition, after an 8-week open-monitoring meditation program. This suggests the presence of a different type of self-awareness in meditation practitioners that is less rooted in one's sense of body and more oriented toward an "impersonal beingness" (Cahn & Polich, 2006).

Effect of Meditation on the Autonomic and Immune Systems

Meditation affects bodily functions in two different ways: standard daily meditation practice creates a low arousal state, and peak meditation experience fosters a high arousal state. According to early theoretical models, infrequent peak experiences have quite a different high arousal tone than the more common meditative states (Cahn & Polich, 2006), but it is difficult to study such experiences because of their rarity. This section will thus only review data concerning the usual trait commonly experienced during meditation practice. Based on early studies of transcendental meditation, Jevning, Wallace, and Beidebach (1992) qualify the common meditation state as a "wakeful hypometabolic state."

The autonomic nervous system controls the activity of organs and viscera in the body. It is composed of the sympathetic and parasympathetic neural pathways. Although this is a schematic view and the reality is far more complex, these two components are usually believed to have opposite actions on their targeted organs or tissues. The sympathetic system is most often involved in energy mobilization, preparing the organism to react (flight-or-fight response, response to stress), whereas the parasympathetic component is responsible for most resting and restoration functions (rest and digestive functions) of the organism (Jänig, 2003).

One possible way for meditation to act on autonomic activity is through respiration control. Respiration is one of the body's few autonomic functions that can be controlled and can affect functioning of the autonomic nervous system (Badra et al., 2001; Eckberg, Nerhed, & Wallin, 1985). Many meditation traditions consider breath, body, and mind to be linked and thus have given, whether explicitly or not, the breath a central role in meditation practice. Voluntary control of the breath may be achieved through specific inhalation-exhalation

rhythmic patterns, as in pranayamic practice and the slow diaphragmatic breathing practiced in yoga that involves specific movement of the thoracic cage. Breath also tends to involuntarily slow down during mantra chanting (Bernardi et al., 2001), breath-counting meditation, and simple awareness of the breath (Lehrer, Sasaki, & Saito, 1999).

Slower respiration rate during meditation practice induces changes in cardiovascular activity that correspond to an increase in the activity of the restorative parasympathetic system (Saul, 1990). This increased parasympathetic activity has also been assessed through the slowing down of basal heart rate in meditators (Pal, Velkumary, & Madanmohan, 2004) and the increased synchronization, or respiratory sinus arrhythmia (RSA), between the breathing cycle and the heartbeat during meditation (Cysarz & Bussing, 2005; Ditto, Eclache, & Goldman, 2006). RSA corresponds to high variability in heart rate as heart rate becomes faster during inhalation and slower during exhalation. Mechanisms behind human RSA are not yet well understood (Grossman & Taylor, 2007; Tzeng, Sin, & Galletly, 2009) but might be important to meditation research, as RSA could be used as an index of successful emotion exposure during meditation (see the section on emotion, below).

Slow breathing has also been associated with increased baroreflex sensitivity (Joseph, Casucci, Casiraghi, Maffei, Rossi, & Bernardi, 2005; Reyes del Paso, et al., 2006). Decreased blood pressure is often reported after meditation practice by both healthy individuals and hypertension patients (Carlson, Speca, Faris, & Patel, 2007; Manikonda et al., 2008). Improved control of blood pressure is usually considered a sign of balance between parasympathetic and sympathetic activity. Finally, since one role of sleep is to restore the balance in these autonomic systems, the fact that meditators typically require less sleep than control subjects (Ajaya, 1976) suggests a better balance between these two systems.

Although few studies have been conducted, there is increasing evidence that meditative practice also affects the immune system. Psychological states such as stress affect the functioning of the immune system (Segerstrom & Miller, 2004). The immune system is indirectly under the influence of the central nervous system via hormonal signaling and through activity of the autonomic nervous system (Dantzer & Kelley, 1989; Jänig, 2003). Davidson et al. (2003) found faster peak rise for the antibody response to a flu shot among healthy meditators who underwent an 8-week mindfulness-based stress reduction (MBSR) training course in open-monitoring meditation than among non-meditators.

Increased number and increased activity of lymphocyte T and other natural killer cells have also been found in HIV patients after MBSR training (Robinson, Mathews, & Witek-Janusek, 2003; Taylor, 1995). Finally, in a recent study, Pace et al. (2009) assessed the effect of compassion meditation (in which one works at developing altruistic emotions and behaviors toward all living beings) on the immune response and found a negative correlation between the amount of meditation practice and induced stress immune response.

We should develop a better understanding of meditation effects on the autonomic and immune systems as we improve our understanding of these systems' relationship and their dynamic links to the central nervous system. Study of slow oscillatory activity in both the central and autonomic systems would likely shed light on coupling mechanisms between the brain, vegetative functions, and the mind (Basar, 2008). Jerath, Edry, Barnes, and Jerath (2006) built a model of synchronization between the cardiopulmonary and the central nervous systems to explain how slow, deep pranayamic breathing practiced in yogic meditation can influence the autonomic nervous system. Davidson et al. (2003) also found that left-sided anterior oscillatory activity of the brain is positively correlated with activity of the immune system after meditation practice, assessing through the quantity of natural killer cells. This type of hemispheric activity has also been correlated with both the autonomic system activity and emotional regulation (Craig, 2005), as we will see in the section dealing with emotions. Thus, although a growing body of evidence showing a link between mind and body states has accumulated over the years, more research will be needed to unravel the mechanisms underlying the effects of meditation on the autonomic and immune systems.

Meditation and Aging

As we have seen, meditation training seems to protect against stress and boosts the immune system. It has also recently been shown to reduce neuronal decay due to normal aging. Pagnoni and Cekic (2007) found greater prefrontal cortex thickness in middle-aged meditators than in non-meditators, as well as a decline in cortical thickness associated with age, a result that is also reported by Lazar et al. (2005). Nagendra, Sulekha, Tubaki, and Kutty (2008) also showed that expert Vipassana meditators did not present sleep patterns associated with aging. Both the length of the slow waves sleep period before the occurrence of the first REM sleep episode and the total length of REM episodes typically decrease with age. They showed that this decrease

was drastically smaller in meditators of age 50–60 than in control subjects of the same age. This suggests that meditation slows down the brain-aging process through a mechanism that has yet to be discovered.

MEDITATION AND ATTENTION

The cognitive function that meditation may affect the most is attention, since meditation is a form of attention training. Meditation is a skill and as such it may train attentional systems. As physical training strengthens body muscles, mental training involved in meditation reinforces brain attentional circuits. Meditation recruits attentional brain areas involved in learning. Using fMRI, a technique that monitors metabolic activity in the brain as reflected by variations in blood flow, Brefczynski-Lewis, Lutz, Schaefer, Levinson, and Davidson (2007) found that in a group of Tibetan Buddhist meditators, focused attention meditation is associated with greater activation in multiple attention-related brain regions (dorsolateral prefrontal cortex, superior frontal sulcus, and intraparietal sulcus). Interestingly, brain activation varied based on the person's level of expertise. Expert meditators had less activity in attention-related brain regions, whereas greater activity among less expert meditators was associated with skill acquisition. This reduced metabolic activity in attention-related regions of highly expert practitioners suggests an effortless—though efficient—strategy for attentional resources allocation. This is supported by traditional Buddhist descriptions of a decreased need for voluntary attentional effort to attain concentration for expert practitioners. Using electroencephalography, Lutz et al. (2004) also found that brain activity varies based on expertise. These results suggest that meditation is a technique that is learned and perfected over years of practice.

According to Lutz, Slagter, et al. (2008), meditation practices involve at least three attention regulation subsystems. First, meditation may involve intense object-based concentration. Selective attention—or orienting—is the selection of specific information from the flow of sensory input and involves cortical structures known to gate information, such as the temporal-parietal junction, the ventrolateral prefrontal cortex, the frontal eye field, and the intraparietal sulcus (Corbetta & Shulman, 2002). Second, meditation imposes continuous monitoring of the focus of attention. Sustained attention—or alertness—is the maintenance of a state of high sensitivity to a perceived stimulus or mental object over time and most likely involves sustained synchronous activity between the thalamus and the right fron-

tal and right parietal cortical structures—also known as the thalamo-cortical loop (Berger, Kofman, Livneh, & Henik, 2007; Coull, 1998; Posner & Rothbart, 2007). Finally, meditation also involves transient attention shifts, as when one disengages attention from a source of distraction and redirects it to the intended object of concentration (Cahn & Polich, 2006; Lutz, Slagter, et al., 2008). This involves executive attention—or conflict monitoring—which is the monitoring and resolution of conflicts among thoughts, feelings, and mental plan. This function is managed by the dorsal anterior cingulate cortex and the dorsolateral prefrontal cortex, structures that have also been shown to be activated when one is self-conscious (Ridderinkhof, Van Den Wildenberg, Segalowitz, & Carter, 2004; Weissman, Roberts, Visscher, & Woldorff, 2006).

Meditation Improves Perceptual Attention Capacity

Perceptual pre-attentive processes are sometimes under voluntary control—as, for instance, when we focus our attention on an object or sound—although they may also be affected by environmental cues. Selective visual attention focused on an object may be involuntarily influenced by the surrounding objects; for example, distracting visual stimuli of high contrast have been shown to automatically redirect this type of attention (Friedman-Hill, Robertson, Desimone, & Ungerleider, 2003). Below, we show how meditation affects involuntary allocation of low-level attentional resources.

In the auditory domain, pre-attentive processes involve the automatic detection of environmental changes and can be studied in the laboratory through the brain's electrical response (event-related potential) to a flow of frequent auditory stimuli interspaced with infrequent ones. The amplitude of the differential electrical activity between frequent and infrequent stimuli, called mismatch negativity, was found to increase immediately among expert practitioners after a focused attention meditation session (Srinivasan & Bajjal, 2007). Similar findings were found for Vipassana meditation (Cahn, 2007). Focused attention training and the higher degree of awareness of the body and sensations induced by meditation might be responsible for increased sensory cortex sensibility. According to one interpretation, neuronal populations tuned to different stimuli inhibit each other and compete for attentional resources (Näätänen, 1992). Neuronal populations tuned to properties of the standard stimulation respond less vigorously upon repeated stimulation and become desensitized. Thus

when a deviant activates a distinct new neuronal population, these fresh afferents respond more vigorously, eliciting mismatch negativity. Meditation would make these perceptual systems sharper and more sensitive.

Experimental work also shows that open-monitoring meditation increases processing capacity in the visual system. This evidence comes from a study using the attentional blink paradigm. In this paradigm, two stimuli are presented in close succession. As a result of allocation of all attention resources to the first stimulus, the second one is often not perceived. However, both behavioral and event-related potential results show that intensive 3-month open-monitoring retreats decrease the attentional engagement in processing the first target, thus allowing subjects to process and perceive the second one (Slagter et al., 2007).

These results indicate that meditation tends to boost low-level attention. This could be due to increased attentional resources. Meditation could recruit new attention-dedicated neuronal networks or strengthen existing ones. Another hypothesis is that attentional resources are constant. However, since meditation tends to quiet the mind, we may observe a disengagement of attention from higher cognitive and verbal areas. If attentional systems are not dealing with thought affects, they might have more resources to deal with low-level perceptual systems.

Meditation Decreases Perceptual Habituation

Neural and perceptual systems tend to habituate to repetitive presentation of stimuli, to which early responses are larger than later ones. Meditation has been shown to decrease perceptual habituation to repetitive stimuli. This type of effect has been mostly observed in open-monitoring meditation, in which the practitioner develops attention to the present moment-to-moment experience without allowing his or her attention to wander. In this meditation, each stimulus is seen as fresh and new in the present moment. As an individual practicing open monitoring works on perceiving each experience as it arises in the moment without judging, it might cut off automatic brain mechanisms responsible for habituation, establishment of routines, and action scenarios. A classical habituation paradigm involves repetitively presenting the same stimulus and observing the decrease in the induced 10-Hz brain alpha wave amplitude with the number of stimulus presentations. Non-habituation was demonstrated with

open-monitoring meditators where the electroencephalographic alpha rhythm amplitude did not decrease after repeated stimulus presentations (Deikman, 1966; Wenger & Bagchi, 1961). These findings are also consistent with Cahn's study (2008) showing less automated recruitment of frontal attentional circuits when rare and salient auditory stimuli are processed during Vipassana open-monitoring meditation practice.

Open-monitoring meditation also allows for faster reallocation of attentional resources. Valentine and Sweet (1999) used an auditory sustained attention task in which participants had to mentally count the number of beeps in several series of tones presented at different rates. In general, fast series came unexpectedly. Open-monitoring meditation resulted in better counting performance in the unexpected fast series. Interestingly, this effect was not observed with focused attention meditation. One explanation is that practitioners of concentrative meditation might have focused intensively on the slow series and may have difficulty shifting their attention to start counting the faster series. On the other hand, open-monitoring practitioners, who only partially practice engaging their attention could more easily shift their attention to the fast presentation rate.

These results indicate that meditation allows for non-habituation and faster reallocation of attention. Beyond low-level attention allocation, we will see now that meditation also has unexpected effects on the activity in higher perceptual areas.

Meditation Reduces Neural Population Competition in Higher Perceptual Areas

Carter, Presti, Callistemon, Ungerer, Liu, and Pettigrew (2005) reported results of a study of 23 Tibetan Buddhist monks who have been engaged in either focused attention or open-monitoring meditation. These monks were asked to perform a "binocular rivalry" task during which they were presented with two images, one before each eye. Under these circumstances, they were randomly experiencing either both images simultaneously or each of them alternatively for 2–3 seconds as the images competed for attentional resources in the visual system. No effects of open-monitoring meditation were observed either during or after the practice. However, monks practicing focused attention meditation were able to maintain a stable, superimposed percept of the two competing images for a longer than normal duration. These results suggest that selective and sustained

attention allows conflicting stimuli to be perceived simultaneously by long-term expert practitioners both during and following focused attention meditation. This also points to the remarkable influence of meditation training on the brain, as no other mental training has been shown to affect allocation of attentional resources responsible for binocular rivalry.

Open-monitoring meditation also seems to allow meditators to more efficiently process stimuli competing for attentional resources. The Attention Network Test has been used to assess open-monitoring meditation influence on attentional subsystems. The test has subjects indicate the direction of a target arrow surrounded by flanker stimuli that either point in the same or reverse direction, thus inducing perceptual conflict (Fan, McCandliss, Raz, & Posner, 2002). Results show that after 5 days of open-monitoring meditation training, participants improved their performance in responding to trials with conflicting conditions (Tang et al., 2007). Both of these experiments show that meditation helps to efficiently process conflicting stimuli.

Meditation and Higher-Level Attention for Monitoring Mind Wandering

What meditation practice brings to awareness is the presence of private thoughts and feelings that constantly pull attention away from its focus. This experience is not restricted to meditation practice. In our normal daily activities—while reading, for instance—we may suddenly notice that instead of being focused on the task at hand, we are focusing on unrelated thoughts and feelings (Schooler, Reichle, & Halpern, 2004). These attentional drifts are termed “mind-wandering episodes” (Smallwood & Schooler, 2006), during which attention transiently focuses on the flow of spontaneous thoughts, what James (1890/1983) called “the stream of consciousness.” The subject is generally not aware of it when mind wandering occurs, and it is only after a certain period of time that he or she becomes aware that his or her attention has drifted. This realization is called meta-consciousness, a re-representation of conscious contents (Schooler, 2002; Smallwood, McSpadden, & Schooler, 2007). The mind-wandering phenomenon highlights two important facts: first, that the quality of focused attention is fluctuating, and, second, that we lack awareness of these fluctuations.

Practice of either focused attention or open-monitoring meditation requires one to keep track of which

object attention is directed at and to bring it back to the object of focus each time it wanders away. This type of training may help someone become aware of mind-wandering episodes and help him or her stay focused on the moment-to-moment experience (Gunaratana, 2002). Mind wandering and meditation are thus two very different—if not opposite—states of consciousness. Mind wandering represents a shift in attention “away from the here and now” toward private thoughts and feelings (Smallwood, O'Connor, Sudbery, & Obonsawin, 2008), whereas the very basis of meditation is being present in “the here and now” without letting one's attention to be distracted by thoughts and feelings (Gunaratana, 2002; Lutz, Slagter, et al., 2008).

In favor of this hypothesis, Farb et al. (2007) revealed distinct fMRI neural activation patterns in control subjects with no meditation training compared to subjects who followed an 8-week open-monitoring MBSR program. Control subjects were primarily experiencing a mental narrative state, where one allows one's attention to be caught by a given train of thought, whereas meditation practitioners were aiming at experiencing moment-to-moment awareness of the self. Mental narrative led to strong activation of the mPFC, and awareness of present experiences led to decreased activation of the mPFC and increased activity in right lateral PFC and right viscerosomatic areas (Farb et al., 2007). Thus there might be two possible types of experience of the self: one—engaged during mind wandering—based on thoughts dealing with past or future experiences of the ego, and one based on the moment-to-moment experience of the self, involving awareness of sensory information from the body. This indicates that the experience of self in the present moment is dramatically different both experientially and in terms of brain activity from the experience of self as projected in the past or the future, as in mind wandering.

Meditation, Mind Wandering, and “Default Network” Brain Activity

The concept of a default mode of brain functioning at rest emerged from the consistent deactivation of a brain area network during a series of psychophysical tasks compared to resting baseline (Greicius, Krasnow, Reiss, & Menon, 2003; Raichle, MacLeod, Snyder, Powers, Gusnard, & Shulman, 2001). The brain network involved in baseline activity includes the mPFC, the dorsal part of which has been associated with self-referential and emotional mental activity (Gusnard, Akbudak,

Shulman, & Raichle, 2001; Ingvar, 1985). Recently, higher activity in the same default network was found during a task with a high occurrence of mind-wandering episodes than during a task with a low occurrence of such episodes (Mason, Norton, Van Horn, Wegner, Grafton, & Macrae, 2007), which suggests that mind wandering could be the main underlying experience of the brain default network. For non-expert meditators, practicing meditation with attention focused on a particular object brings to awareness how frequent and pervasive mind-wandering events are. Sonuga-Barke and Castellanos (2007) proposed a hypothesis to explain the presence of mind-wandering events. Fluctuation in the quality of sustained attention, (i.e., the occurrence of mind-wandering events while one is focusing on a task) could be in part due to interference with the default mode of brain activity. In this model, interoceptive and exteroceptive attentional focus are slowly but continuously fluctuating at rest, so as to allow individuals to perceive the environment and process it cognitively. Engagement in a task (exteroceptive attention) first attenuates interoceptive attention, although with time, activity in interoceptive attention network components gradually returns, leading to episodes of mind wandering. Long-term effects of meditation training could be enhanced capacity to inhibit introspective spontaneous activity during sustained attention engagements through modification of large-scale neuronal network connectivity and activity (Lutz et al., 2008).

Consistent with this hypothesis, electroencephalography shows spontaneous fluctuations between two distinct and supposedly opposite modes during resting-state brain activity (Laufs et al., 2006). One of these modes is characterized by the presence of slow oscillations of 3–7 Hz (theta activity), which are associated with reduced level of vigilance. The other mode is characterized by the presence of fast oscillations of 12–30 Hz, which are usually associated with high vigilance levels. These spontaneous patterns of increased and decreased theta activity have recently been associated with periods of mind wandering and periods of concentration, respectively (Braboszcz & Delorme, 2009; Cahn, 2007). The hypothesized association between different vigilance levels and mind-wandering and meditation is also supported by EEG studies based on event-related potential analysis. These studies reveal that mind wandering is associated with a reduced capacity for processing external events, as assessed by a decrease in amplitude of the brain's electrical response in this state (Smallwood et al., 2008), whereas meditation is associated with increased sensory information

processing (Cahn & Polich, 2009; Srinivasan & Baijal, 2007). Thus, mind wandering tends to disconnect people from their environments, whereas meditation tends to sharpen their perceptions of it.

While meditation practice benefits psychological well-being, mental states with a high frequency of mind-wandering episode, such as depression or boredom, are experienced negatively. Carriere, Cheyne, and Smilek (2007) found that frequent brief lapses of attention, that is, lack of conscious awareness of one's action, is associated with proneness to boredom and depression among students. More frequent and intense periods of mind wandering during a word-encoding task have also been linked to dysphoria (Smallwood et al., 2008). On the other hand, an open-monitoring meditation offered to students during a month of MBSR intervention reduced their psychological distress as well as their ruminative thoughts (Jain et al., 2007).

MEDITATION AND EMOTIONS

Regardless of the specific meditation technique, meditation leads to state and trait experiences involving a deep sense of peace and calm. In fact, achieving enduring happiness by freeing oneself from affliction is the central doctrine of Buddhism (Ekman, Davidson, Ricard, & Wallace, 2005). The fact that meditation affects the way emotions are experienced and allows for better regulation of negative and distressing feelings is in part an outcome of meditation-induced changes on body, brain, and cognitive functioning.

Emotions may be seen as a set of interrelated changes in the body in response to a real or imagined situation or stimulus. Emotions are experienced as feelings and may interrupt ongoing behavior or mental processes in to the form of an urge to engage in action (e.g., flight for fear, outburst of anger), depending on the emotion felt (Hamm, Schupp, & Weike, 2003). Emotions elicit responses and changes both in the body and in the attentional systems. Increased processing of body sensory inputs might also affect the way emotions are first perceived through somatosensory information. Increased concentration results most likely in better control of mind wandering; that is, enhanced attention and better resistance to distraction might reduce emotional reaction by reducing negative emotions' propensity to interrupt the ongoing stream of thoughts and behavior. Changes in attentional capacities are also most likely linked to changes in brain activity, especially in the anterior areas, in which neural activity has been linked to

the functioning of the autonomic and immune systems, which are known to be affected by meditation.

The Links Between Brain, Body, and Emotion

In the last 20 years, asymmetries in brain electrical activation have been linked with the way people react to emotional situations and regulate their emotions (Allen & Kline, 2004; Wheeler, Davidson, & Tomarken, 1993). In individuals who tend to react positively and let go quickly of negative emotions, the baseline electrical activity of the brain exhibits greater left-sided anterior activation than recordings of individuals who are more prone to nourishing negative emotions (for a review, see Davidson, 2004). After 6 months' practice of mindfulness and MBSR meditation, healthy participants showed enhanced left-sided prefrontal electrical activity in the alpha band after induction of both positive and negative feelings (Davidson et al., 2003). The same study found increased left-sided PFC activity to be associated with reduced anxiety and negative emotional reactivity as well as increased experiences of positive affect. These results correlate with previous ones demonstrating that people with more left-sided baseline activation in the PFC have a more positive outlook on life than individuals with right-sided PFC activation (Davidson, 2000).

The relationship between positive affect and anterior brain areas activity is strongly supported, as reviewed by Craig (2005), by the anatomical connectivity between the autonomic system and anterior brain areas. Craig demonstrates clearly how the left anterior part of the brain interacts more directly with the parasympathetic system and the right anterior part interacts more directly with the sympathetic system. Activity in either of the hemispheres is thus associated with behavior and emotions in accordance with the opposite actions of these two components of the autonomous nervous system. Thus left-sided activation would correspond to more enriching emotions, that is, those eliciting positive, group-oriented behaviors, whereas right-sided activity would imply activity of the sympathetic system and thus reactions associated with negative, aversive behaviors.

Meditation and the Regulation of Emotions

During most meditation practice, practitioners are encouraged to keep a balanced, nonjudgmental state of

mind. Practitioners can achieve this by experiencing feelings as they arise in the mind, then stay for a period of time, and later pass away. While meditating, practitioners in most meditation traditions are instructed to keep a calm, balanced mind, noticing affects with no feeling of aversion toward unpleasant emotions or feelings of desire for pleasant, enjoyable ones.

Contemporary research on emotion outlines two means through which emotion regulation may be achieved: attentional control and cognitive control (Ochsner & Gross, 2005). Attentional control involves manipulating the amount of attention that is naturally allocated to process emotional stimuli. Exercising cognitive control involves changing expectations or judgments about emotional stimuli. Both of these strategies are supposedly present in meditation, whether attention is focused away from the emotion (such as in concentrative practices) or the emotion is simply being observed (such as in contemplative mindfulness practices). Cognitive control is also achieved indirectly: as meditators gain insight into their minds and bodies, their appraisal of emotion automatically evolves. In addition, meditation may also change emotion's appraisal by changing the practitioner's beliefs about the world.

The way meditation modulates pain perception may provide a good overview of how meditation affects the process through which emotions give rise to specific feeling. Pain is defined as an "unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (International Association for the Study of Pain, 1994). Recently, pain has been described in terms of a homeostatic emotion, that is, as a feeling from the body (like thirst or hunger) that elicits a specific behavior to preserve body equilibrium (Craig, 2003).

Numbness and pain that arise from long periods of sitting without moving is a common side effect of meditation practice during retreats. Constantly changing position whenever pain arises would disturb meditation, so meditators are asked to use different strategies to cope with pain. According to Gunaratana (2001), it is best to adopt a voluntary and focused attitude of simply watching the pain—that is, experiencing the pain without identifying with it. Practitioners may also try to lessen the importance of the pain by comparing it with the pain that one experienced previously in one's own life, or pain that others are experiencing. Another strategy would be to divert the attention toward another object, such as the breath, and as a last resort to slowly stretch the muscles to see if the pain can be lessened.

It is said that with practice, it takes more time for pain to arise and that it becomes less intense. This resistance to pain, which is a major component of meditation retreats, probably helps meditation practitioners cope with their own suffering in a more detached way after the retreat is over.

Treatments of chronic pain based on diverse meditation practices, such as MBSR programs (Kabat-Zinn, Lipworth, & Burney, 1985; Morone, Greco, & Weiner, 2008) and loving-kindness meditation (Carson et al., 2005), have revealed positive outcomes associated with improvement of overall quality of life. Enhanced tolerance of acute pain has also been assessed in different studies with both focused attention and open-monitoring meditation. Longitudinal study of transcendental meditation shows decreased brain activation in the thalamus, prefrontal cortex, and anterior cingulate cortex in response to acute pain (immersion of the hand in hot water) after 5 months of TM daily practice in participants who were new to meditation (Orme-Johnson, Schneider, Son, Nidich, & Cho, 2006). This study further suggests that TM practice does not change actual pain sensations (as pain rating didn't change pre- or post-TM practice and never significantly differed between beginners and long-term practitioners) but does reduce emotional distress associated with pain, resulting in enhanced tolerance of acute pain. Results of this last study are of particular significance, as they highlight meditation's effects on the regulation of the distress associated with painful feelings. Thus meditation practice changed the way individuals reacted to the emotion related to pain. In fact, meditation seems to be acting at the feeling level, in the way pain sensations are experienced subjectively as emotions. One hypothesis is that meditation training that involves developing a nonjudgmental attitude leads to change in emotion representation, resulting in less body and mental disturbance.

In fact, the different forms of self-consciousness experienced during meditation (Farb et al., 2007) and the emphasis placed on equanimity and body sensations suggest that meditation leads to a different appraisal of somatic markers than the common normal state. According to the somatic marker hypothesis of Damasio (1994), emotions mark our experiences in terms of body representation, and these somatic markers are then used to evaluate new situations and experiences. Feelings are based on bodily response and precede emotions, which are viewed as mental reactions to feelings. In this framework, keeping a nonjudgmental state of mind during meditation could delay or attenuate emotional reactions to feelings.

Meditation and Brain Imaging

The regulation of emotions, especially of negative ones, has been extensively studied using brain-imaging techniques. Studies show that meditation actually affects two important areas of the brain emotion circuitry: the amygdala and the PFC. The amygdala is engaged in producing autonomic, endocrine, and somatic responses as well as directing attention toward affective stimuli that are potentially important, such as potential threats or potential sources of food (Davis & Whalen, 2001). The PFC down-regulates neural activity in the amygdala and the two areas share reciprocal connections (Banks, Eddy, Angstadt, Nathan, & Phan, 2007; Davidson, 2002). Less body arousal and EEG brain activation has been observed in response to negative affects for yoga practitioners (Aftanas & Golosheykin, 2005). Consistent with this, when one is engaged in focused attention meditation, fMRI studies show that amygdala activity in response to emotional negative or positive sounds is decreased in long-term Tibetan expert practitioners compared to novice ones. Interestingly, the more hours participants have spent meditating in their lifetimes, the more important is the decrease in amygdala activity (Brefczynski-Lewis et al., 2007). However, fMRI studies show that when engaged in focused compassion meditation, expert meditators from the same tradition exhibited greater amygdala activation in response to emotional stimuli than novice practitioners (Lutz, Brefczynski-Lewis, Johnstone, & Davidson, 2008).

These seemingly opposite results suggest that meditation allows for a wider range of emotional experiences, and that these experiences can be modulated through the practice of specific meditation techniques. Greater embodiment or disembodiment of emotions can be achieved through voluntarily modulation of dedicated attentional circuits that have been intensively trained through meditation practice. Consistent with this hypothesis, subjective reports indicate that meditation seems at first to intensify the experience of positive as well as negative feelings. Then through practice, these intense feelings are accepted and might contribute to the experience of a richer internal life, as reported by meditation practitioners.

Taken together, brain-imaging results support the empirical hypothesis of meditation-induced emotion regulation and suggest that it involves brain plasticity. The regular practice of meditation affects the connections between the emotional limbic system and the neocortex in such a way that it would change the individual's thoughts about and interpretation of negative emotions (i.e., his appraisal of his emotion).

CLINICAL APPLICATION OF MEDITATION FOR EMOTION REGULATION

The beneficial effects of meditation on the appraisal of negative emotions have been observed in clinical practices. As we will see, meditation practice has been shown to reduce alexithymia—difficulty recognizing and expressing emotions associated with operative thought processes (Sifneos, 1973)—through development of emotional intelligence and insight into one's emotional functioning (Baer, Smith, et al., 2004).

Appearance and inclusion of meditation in clinical practices is coincidental with the rise of the “third wave” of psychotherapies. The third wave accords particular importance not only to emotions but also to the context of those psychological phenomena and to their functions (S.C. Hayes, 2004). The third wave rises in response to cognitive-behavioral therapy (CBT), a pure dialectic approach that has been successful placing emotions in their proper context but remains limited because of the large number of complex protocols. Today, working with emotion regulation is the core process for approaching and curing mental disorders (Barlow, Allen, & Choate, 2004; Campbell-Sills & Barlow, 2007), and we are currently observing a unification of all cognitive-behavioral therapy protocols with the inclusion of the core concept of mindfulness (Allen, McHugh, & Barlow, 2007). Emotion regulation, even the regulation of extremely intense emotions resulting from trauma (Brillon, 2006), is realized through a three-step process: first feeling the body sensation (arousal), then identifying and labeling emotions that arise from both arousal and appraisal, and finally accepting the emotion in a non-judgmental way. This last step of accepting one's own thoughts and cognitive traits has been developed by S. C. Hayes et al. (1999) in meditation-based acceptance and commitment therapy. Any clinical intervention should rely on theory on addressing these three stages.

Here we first present the nature and function of emotions as well as a model of how they operate. We subsequently articulate our meditation intervention on this model.

The Emotion Apprehension Process: How Emotions Can Become Pathological

Simple principles about emotions must first be reviewed: emotions generate body (arousal) and thought

(appraisal) responses (Frijda, 1986). Emotions may be useful for attaining a better response to a situation, even when they are negative (Hahusseau, 2006). In fact, patients with lesion in the ventro-median prefrontal cortex, the amygdala, or the insula, which are three important emotional brain areas, have difficulties with decision making (Bar-On, Tranel, et al., 2003). These lesions result in an incapacity to react appropriately to life events or in social contexts. This emotional intelligence deficit has been shown to be based in a neuronal system that is independent from the one supporting cognitive intelligence (Bar-On, Tranel, Denburg, & Bechara, 2003). Used at their best, emotions are felt, labeled, and accepted. If one step is missing in this process, emotions lose their power as a signal and become toxic for the mind and body.

The following metaphor will help us fully understand the need for each step in the emotion apprehension process and the potential danger of ignoring one of them: consider a wound in the sole of the foot that causes great pain when you walk barefoot on the sand. There are different possibilities for how to deal with this situation:

- (1) The pain is so intense that you take a high dose of analgesic. The medicine is effective and the pain disappears. For a few minutes after, you are careful not to walk on the wound. Then you forget about it and walk on the anaesthetized injured foot, worsening the depth and seriousness of the wound. This problem occurs because you have dissociated yourself from the pain and do not feel the wound anymore.
- (2) You feel the pain but haven't identified its origin. You believe it's a scratch and place a bandage on it without removing the piece of dirty broken glass lodged in the foot. The wound gets infected and worsens. This problem arises because the nature of the wound was not adequately identified.
- (3) You feel the pain and have identified its origin but feel scared. You refuse any examination by a doctor for fear that it will be too painful or you refuse to go to the hospital, arguing that you do not have time. The wound gets infected and you are immobilized for a long period of time. This problem arises because you did not accept the wound.

The types of possible reaction we considered for a physical wound are also present for negative emotions. If one does not feel one's emotions (i.e., dissociative disorder), does not identify them (i.e., alexithymia), or does not accept them (i.e., emotion intolerance), analgesic effects can provide short-term relief, but mental and physical health are affected over the long term.

The Three Majors Emotional Disorders

Each of the three following emotional regulation disorders corresponds to an anomaly or blockage in the process of the emotion arising, developing, being experienced, and eventually vanishing. They are at the origin of most mental disorders and very often are intertwined. Taking them into account is thus of primary importance in therapeutic approaches.

Dissociative Disorder

The absorption experience, experienced by 80% of people when reading or watching a movie, and different forms of dissociative disorder as described in *DSM-IV-TR* (DSM-IV, American Psychiatric Association, 2000) have common characteristics: the narrowing of both consciousness and perceptual fields. In its most spectacular form, it can result in multiple personality disorder or dissociative fugue. "Dissociation is a process where the usually integrated functions of consciousness, memory, identity or perception of the environment are spontaneously disrupted and certain mental events that are ordinarily processed together (e.g., thoughts, emotions, sensations, etc.) are isolated from one another" (DSM-IV, American Psychiatric Association, 2000, p. 167).

Dissociative patients commonly have particular difficulty adapting to new situations and to establish daily routines such as choosing a regular schedule for eating or sleeping. They are poorly connected to their internal sensations and barely feel pain and other body sensations, such as their heartbeat or breathing. Dissociative patients don't adapt to day-to-day reality; they don't pay attention to directions when going from one place to another and listen to but don't comprehend conversations. There are people and objects in their homes that they know or have seen but don't remember. In general, they have few memories, even of important life events, and they doubt the veracity of those memories they do have. These persons live exclusively in the mind; they do not have feeling of themselves and are unable to focus on the present moment. If placed on a continuum, dissociative disorder and mindfulness would be at opposite ends, mindfulness being the capacity to be aware of the moment-to-moment unfolding experience while keeping a nonjudgmental attitude (Kabat-Zinn, 2004).

Dissociative disorder affects about 10% of the population (Foote, Smolin, Kaplan, & Legatt, & Lipschitz, 2006; Ross, 1991). Dissociative disorder is often associated with difficulties controlling impulsivity, chronic pain syndrome, and fibromyalgia. It is also preponderant in patients suffering from mental disorders such as

depression, anxiety disorder, addiction, anorexia, and binge eating (Valdiserri & Kihlstrom, 1995) as well as personality disorders. The most frequently associated comorbidities include borderline personality disorder and post-traumatic stress disorder (Dell, 1998).

Alexithymia

Difficulty identifying emotion, which is characteristic of alexithymia, comes from the inability to express emotions to others (Taylor, 1984). Alexithymic patients tend to be inexpressive and emotionally "restricted" and have difficulties bonding with others (Taylor, 2000). The occurrence of separation and divorce is higher in this population than in the normal population. Alexithymia as evaluated with the 20-items Toronto Alexithymia Scale (Bagby, Taylor, & Parker, 1994) affects about 15% of the general population with a slight over-representation of men.

This disorder is often associated with personality disorders addiction to substances such as alcohol, toxics, and sedatives and eating disorders like binge eating. It is also often associated with somatic disorders (arterial hypertension, anger, asthma, etc.).

Emotional Avoidance

Even when they are suited to life circumstances, negative emotions (sadness, fear, shame, anger, stress) may generate stress if one does not feel one has control over them. They may also generate fear (that they will never end) or shame (at the idea that one is the only person to whom this happens). In these cases it is not one but two emotions that distress the mind and body (Greenberg, 2002). In a sense, it becomes twice as hard to cope with emotions (see Figure 27.2). Thus negative emotions like sadness and anger that should be restricted in time turn into long-lasting negative moods such as depression or sustained resentment. Since negative emotions are often experienced as pain in the body, secondary emotions (Greenberg & Paivio, 1997) might lead to the development of chronic pain.

Patients who experience emotional avoidance can have four types of fearful ruminating thoughts: (1) fear that the emotion will never end; (2) fear that the emotion will lead to loss of control over behavior; (3) fear of other people's judgments; (4) the fear that intense body arousal that results from the emotion could be a major disease (Williams, Chambless, & Ahrens, 1994). When an emotion is perceived as bearable and is accepted, no conscious effort is made to suppress it, and mood stabilizes spontaneously. Conversely, efforts to suppress

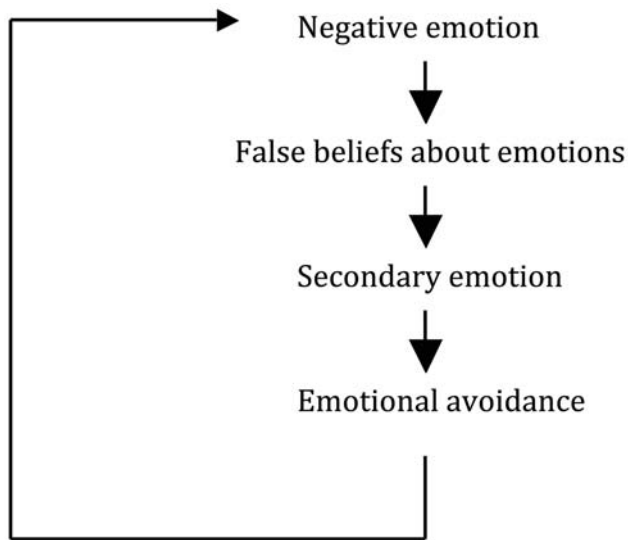

Figure 27.2 Emotional intolerance model.

emotions exacerbate them and are at the core of most mental disorders.

Since this disorder has only been recently identified, there is no real estimation of its frequency of occurrence in the general population, although Barlow argues that it is responsible for most mental disorders (Barlow et al., 2004).

Meditation-Based Emotion Regulation

The new meditation-based approach to emotional dysfunction emphasizes the advantages of the development of body perception of emotion, then identification and acceptance through meditation (S. C. Hayes, 2004). Thus, for example, in moving meditation such as yoga, what seems to be efficient in regulating emotion is self-observation, concentration, and acceptance; during this process attention is placed on sensations, and impermanence acts as a background mind-set (Campbell & Moore, 2004). Talk therapy (purely intellectual therapy) seems more limited: “The absence of direct connections from the PFR-L to the amygdala may be related to why talk therapy for psychiatric conditions that involve amygdala-related conditions is relatively inefficient (in terms of the amount of time required to achieve a therapeutic effect)” (LeDoux, 2002, p. 292).

Meditating is thus a way to deal with dissociative disorders through the development of a mindful attitude. It is also a way to deal with alexithymia in that it helps patients increase emotional intelligence and enhance their emotional tolerance through exposure

to emotions. Different types of thoughts suppression in all mental disorders are causal factors in the long-term increase of emotional arousals and appraisals (Levitt, Brown, Orsillo, & Barlow, 2004). Meditation thus can be used to prevent the use of avoidance strategies, which involve physiological arousal (interoceptive), avoidance and cognitive avoidance (use of other thoughts as distraction), procrastination and worrying (avoiding emotionally salient tasks), and rumination in depression (Nolen-Hoeksema, 2000).

Meditation-Based Protocols and Depression

Medication-based therapy as well as psychotherapies (cognitive therapy and interpersonal therapy) are successful in curing punctual depressive episodes but fail to prevent relapses. After three major depressive episodes, the probability of relapse is about 90%. In addition, the continued use of antidepressant over several years may be problematic because of the presence of side effects and addiction issues. Finding alternative treatments has become critical, especially since the World Health Organization predicts that in 2020 depression will be ranked the second most common illness worldwide. Meditation-based clinical intervention can help tackle this major health care issue.

About 40 studies have shown that, once treated with a meditation based protocol, patients do not differ from subjects without depressive history in regard to the amount of negative thoughts they have (Ingram, Miranda, & Segal, 1998). Instead of studying thoughts’ effects on mood, some researchers have also studied mood’s effects on thoughts. For example, Teasdale (1983, 1988) showed that experience-induced sadness (induced by sad music or sad reading material) had more impact on subjects with a history of depression than on control subjects (Segal & Ingram, 1994). Negative emotions thus seem to have a more lasting effect in subjects who have suffered from depression. Reactivation of negative thoughts in these subjects preserves and deepens sad moods through a series of vicious cycles. Sad moods can thus generate lasting negative thoughts to the point that a slight mood impairment for these patients can trigger disastrous changes in thought patterns and can be responsible for the persistence of depression and relapses.

Cognitive reactivity describes the ability of a slight change in mood to degenerate into a series of deeply negative thoughts. Cognitive reactivity has a cumulative impact: each depressive episode increases the probability of a new one since, with time, the depression circuitry

is more readily activated. Early depressive episodes are most often preceded by significant negative events but as new episodes occur, the role played by these events becomes less clear. Each new episode seems to lower the threshold for depression onset. With time, this threshold tends to get so low that depressive episodes seem to occur spontaneously. Even when an episode of depression is over, cognitive reactivity remains and puts the patient at risk of suffering another episode. Changing a person's relationship with his or her own thoughts and negative emotions—in a way that doesn't directly act on the content of thoughts—is key to stopping the vicious cycle of cognitive reactivity.

Jon Kabat-Zinn relied on mindfulness-based practices to put distance between the patient and his cognitive, emotional, and sensory experiences (Kabat-Zinn, Lipworth, Burney, & Sellers, 1986; Kabat-Zinn et al., 1992). Kabat-Zinn's mindfulness-based stress reduction program has become widely popular since about 1970 and is now often accepted in clinical settings. MBSR is a structured group program composed of 8 two-hour weekly sessions. Sessions are centered on mindfulness practice (simple Zen-like mindfulness meditation) and experiential feedback. Participants commit to practice at home for 45 minutes daily, at least 6 days a week. MBSR has been shown to be efficient for stress reduction (Davidson et al., 2003). Mindfulness-based cognitive therapy (MBCT) is largely based on Kabat-Zinn's stress reduction program and has the same format as MBSR except that it makes use of cognitive therapy in addition to meditation (McQuaid & Carmona, 2004). MBCT therapy has proved to be efficient, as it reduced the probability of relapse by about half among patients who had experienced at least three major depressive episodes (Michalak, Heidenreich, Meibert, & Schulte, 2008; Teasdale, Segal, Williams, Ridgeway, Soulsby, & Lau, 2000).

Here is how Kabat-Zinn (1990) describes the emotional detachment process: "It is remarkable how liberating it feels to be able to see that your thoughts are just thoughts and that they are not 'you' or 'reality' . . . The simple act of recognizing your thoughts as thoughts can free you from the distorted reality they often create and allow for more clearheadedness and a greater sense of manageability in your life" (pp. 69–70). Mindfulness thus provides a method for detachment that turns into recognizable changes in mood. Kabat-Zinn's mindfulness does not teach people how to avoid unpleasant emotions and life events: it only proposes to teach people how to live with them.

Thus asking patients to perform a particular task (i.e., meditation) when negative thoughts cross their mind may help them to abstain from totally identifying

with these thoughts. It automatically puts some distance between the patient and his or her negative thought-affect and allows the patient to tolerate these thoughts better. It also absorbs the patient's focus of attention and the limited information-processing resources of the brain, thus allowing the patient to avoid the ruminative loops of thought-affect. Eye movement desensitization and reprocessing (Shapiro, 1999), a technique that involves performing repetitive eye movement while recalling traumatic events, most likely works on the same principle, although it lacks the emotional intelligence component that is characteristic of meditation-based interventions.

Meditation-Based Emotion Exposure

Meditation protocols are powerful clinical interventions and should not be taken lightly. For instance, some form of concentrative meditative practices could lead to emotional avoidance, as they instruct practitioners to direct their attention to a specific object while ignoring all others, including negative thought-affect. They could thus train patients to avoid negative thought-affect, leading to with potentially significant consequences.

MBSR and MBCT are suitable to use to prevent relapses in depression but require adjustments when applied to intense negative emotions in patients with emotional trauma. The procedure used in these practices could lead to a form of emotional avoidance, as the attention is intentionally and plainly redirected toward specific emotional material. Below, we provide an adaptation of these practices that relies on breath awareness meditation (a basic form of meditation inspired from Zen and Vipassana), which is less abstract and easier to achieve than mindfulness for beginners.

The meditation-based emotion exposure (MBEE) protocol has been described by Hahusseau as grouping together all elements of the emotional psychosomatic process. It is mostly inspired by MBSR and MBCT. However, MBCT and MBSR involve standard meditation followed by cognitive assessment. In contrast, MBEE, like acceptance cognitive therapy and eye movement desensitization and reprocessing, places the emotion at the center of the meditation practice.

- (1) Chose a target emotion and assess the discomfort it creates here and now on a scale of 1– 10. It can be:
 - A pervasive negative emotion
 - A painful sensation
 - The image of a recurrent memory
 - An intrusive and compulsive thought or belief
 - A worry

- (2) Put yourself in respiratory sinus arrhythmia by
 - (a) Isolating yourself
 - (b) Closing your eyes
 - (c) Placing your attention around the nostrils, the ribs, or the abdomen without trying to slow down or change your breathing, but simply observing your breath and breathing sensations
 - (d) Trying to feel both your cardiac rhythm and respiratory movements in the same areas of the body.
- (3) Use the following guidelines to expose yourself to emotions for at least 30 minutes while keeping the eyes closed. The only goal here is to follow your attention and to be aware of where it goes, while remaining aware of the breath. Whatever thought arises in your mind or sensation in your body, simply observe it, without judgment, and with the kindest and most compassionate attitude possible (Lutz et al., 2004; Neff, 2004), without any desire to change it or to ease the pain, simply following the breath until the breathing cycle is complete.
 - (a) Intentionally direct your attention toward the target emotion until your attention becomes attracted by another thought, emotion, or object.
 - (b) Observe, without any judgment, where your attention is being drawn.
 - (c) It is possible that you might experience a physical sensation. In this case, follow the breath toward this sensation, not trying to stop or resist it, but simply trying to feel it. If it is painful, simply observe how much pain you feel.
 - (d) If your attention is attracted by some mental content—a thought, a memory, a worry, a question—observe this content as if it were written on a screen and at the same time feel what happens in the body. What bodily sensation is present? Observe how much this thought and its associated feeling proves that you are suffering now. Try to label the emotion you are experiencing (sadness, anxiety, anger) and stay in touch with it.
 - (e) If you realize your attention is lost in other thoughts, begin again, using the initial target emotion.
- (4) After emotion exposure:
 - (a) Assess again the discomfort you feel on a scale of 1–10.
 - (b) Briefly write down what you observed during the exercise.
 - (c) In the following hours, observe if anything has changed since before the exercise.

Clinical Application of the MBEE to Binge Eating Disorder

Following a failure of classic behavioral therapy with a patient suffering from an eating disorder, Hahusseau tested the meditation-based emotion exposure protocol described above. The literature shows that 20%–50% of patients with eating disorders have a traumatic history, such as sexual abuse during childhood. Traumatic history is neither sufficient nor necessary for an individual to develop an eating disorder. However, it is known that a combination of abuses, such as an unfavorable family environment (Vanderlinden & Vandereycken, 1997), significantly increases the probability of binge eating (Hastings & Kern, 1994).

It is hard for eating disorder patients with traumatic histories to regulate their emotions (Van der Kolk, Pelcovitz, Roth, Mandel, McFarlane, & Herman, 1998). Self-mutilation and addiction to benzodiazepine or alcohol are found in 70% of eating disorder patients with a traumatic history, but in only 15% of eating disorder patients without a traumatic history (Gleaves & Eberenz, 1994). The frequent combination of abuse (Barker-Collo, 2001), dissociative disorder (Maaranen, Tanskanen, Haatainen, Koivumaa-Honkanen, Hintikka, & Viinamaki, 2004), and eating disorders (L. Brown, Russell, Thornton, & Dunn, 1999) eventually led Hahusseau to offer her patients MBEE.

Here we describe two case studies that illustrate use of the protocol and demonstrate its potential efficacy. Some studies have already started investigating the benefits of meditation for eating disorders, particularly for binge eating disorder (Kristeller & Hallett, 1999), and protocols were judged to be “most likely efficient treatments” (Baer, 2003, p. 129). MBEE involves first collecting anamnestic data (patient history), then training the patient to perform the emotion exposure protocol and guiding him or her through it. The protocol has been split in two sequences: past-emotion exposure sessions are done at the therapist’s office and current-emotion exposure sessions are done twice with the therapist, then at home by the patient on his or her own.

Françoise

Françoise was married with two kids. She was 52 years old and 5 feet 7 inches and weighed 233.2 lbs for 20 years. Françoise was a nurse and had a history of postpartum depression. She wished to see a therapist for binge eating disorder and her uneasiness at work. She had already done two 8-year-long psychotherapies. Her weight anamnesis revealed that her father called

women “fatty” and she gained considerable weight after her children’s birth. She snacked excessively and was not physically active. At work she felt insecure during planning discussions, and she always agreed to do the most demanding tasks. Her colleagues disliked her and saw her as too obsequious. She was aware that her fear of her colleagues’ criticism was unreasonable and that her behavior was not appropriate but she did not seem to be capable of changing it. She did not dare say “no”,

The primary therapeutic hypothesis was the following:

- Her social situation leads to negative emotions.
- Negative emotions lead to assertion disorder and submission.
- Assertion disorder and submission lead to dissatisfaction.
- Dissatisfaction leads to snacking.
- Snacking leads to more negative emotions.

The therapeutic plan initially consisted of the behavioral exercise of positive self-assertion (Stravinsky, Marks, & Yule, 1982). Although she was motivated to complete the assignments and was consistent in doing so, the first 30 sessions did not provide satisfying results. She failed to successfully assert herself and her intense negative emotions remained unchanged. She still could not express herself at work. No weight change was observed during this initial therapeutic approach.

She then tried MBEE. The chosen past emotion related to her father beating her brother in front of the whole family. Françoise experienced repetitive traumatic reliving of scenes between her father and brother. As the youngest child in her family, she had felt neglected growing up. Her mother’s submissiveness and father’s inflexibility and violent fits also added to her feelings of insecurity. As a child, her primary emotion (Damasio, 1994) or behavioral tendency (Frijda, 1986) was passive submission. Since then she had suffered from dissociative disorder.

Recalling the violent scenes between her brother and father produced anxiety, extreme insecurity and helplessness, and feelings of guilt, sadness, and anger. During the emotion exposure protocol, her somatic response was severe and involved abdominal pain and accelerated breathing rate. She rated her reaction as 7 on a 1–10 subjective intensity scale. The emotion exposure protocol allowed her to release these intense emotions and other emotions associated with traumatic memories, such as her sexual molestation by a doctor, her father’s insults when she was 18 years old, and eventually her brother’s suicide. The total exposure consisted

of 30 session of 1 hour each with two sessions devoted to learning the protocol so she could practice emotion exposure at home on her day-to-day experiences.

Within a year Françoise lost about 66 lbs; she is now involved in sports and is happy to feel her body again. At work she is now at times assertive, expresses her feelings, and no longer runs away from conflict. She is now more accepting of herself. Today, after 3 years, she still weights 167 lbs.

Anabelle

Anabelle was a 45-year-old seamstress. She was 5 feet 3 inches tall and weighed 211 lbs. She wanted to consult a psychiatrist for problems in her relationship and for her eating disorder (for which she was also considering gastric bypass surgery). She and her twin brother were the youngest in a family of six children. Her mother had been diagnosed with psychosis. Anabelle was divorced with two children ages 20 and 24. She had been in treatment for 5 years and regularly used benzodiazepines to ease her anxiety. Her treatment at the onset of the emotion exposure protocol was Seltraline-50 once a day and 10 drops of haloperidol. Her eating disorder had begun a year prior to her divorce, when she was 32. Her weight had increased ever since, and her behavior reflected her shame: she would close the door of her home quickly so the neighbors would not see she was overweight. She had one eating crisis per day, she seemed to be emotionally unresponsive, and her colleagues at work rejected her. She had had a difficult childhood and was often kept awake by her psychotic mother’s scream at night. She and her siblings regularly experienced violent attacks by her father. At 10 years old, she was sexually abused by her brother-in-law and, as a result, suffered from dissociative disorder. When she recalled this traumatic event, she rated it as 6 on a 1–10 pain scale.

Anabelle attended a total of 20 sessions: 10 sessions of 30 minutes for data collection and functional analysis, then nine 1-hour sessions dedicated to MBEE targeting the traumatic event, and finally a 2-hour session dedicated to learning the technique so she could learn it at home on her day-to-day emotions. After the second emotion exposure session, Anabelle started to lose weight without effort.

She now weights 172 lbs and has changed her mind about having gastric bypass surgery. She regulates her emotions by crying. She once again feels her body, can experience satiety, and believes she is making progress addressing her dissociative disorder. She decided to stop taking antidepressants during the emotion

exposure treatment. Today, after 6 months, she has not regained weight.

Toward an Objective Marker of Emotion Exposure

Emotion regulation describes an individual's capacity to adjust from a high arousal level produced by sympathetic nervous system activity to a less elevated one, which depends on the parasympathetic autonomic nervous system (Gross, 1998). Some measures of autonomic system activity such as heart-rate variability (HRV) can thus be used to assess emotion regulation. As we have seen, one primary effect of meditation is to spontaneously activate the parasympathetic system. Systematic observation of patients' HRV recordings during the MBEE revealed that each of its steps (feeling, labeling, compassionate acceptance) influenced the 2- to 3-second cycle sinusoid component of heart-rate variability. In the meditation-based emotion exposure protocol, the unique instruction given to the patient is to observe without judgment—and while breathing—his or her emotional, cognitive, imaginary, sensorial material.

Various meditation practices have been reported to induce an overall increase in HRV (Bernardi et al., 2001; Cysarz & Bussing, 2005; Ditto et al., 2006; Lehrer et al., 1999; Phongsuphap, Pongsupap, Chandanamatttha, & Lursinsap, 2007; Takahashi et al., 2005), which is most often interpreted as an increase in parasympathetic over sympathetic activation. The protocol could help suppress cortical influences on the sinus node that could disturb the heart's autonomic regulation (Craig, 2005); however, tasks that involve changes in respiratory rates must be carefully analyzed to avoid flaws in HRV interpretation (Grossman & Taylor, 2007). Furthermore, in dissociative disorder patients, it is possible to observe in the HRV time series a decrease in activity of the autonomic nervous system, as shown by a study of skin conductance measure (Sierra et al., 2002). HRV would then reflect activity from efferences of the central autonomic network (Thayer & Lane, 2000) and could be used to measure the presence of voluntary control over emotions, called avoidance, or its absence, called acceptance.

Though further study is necessary before a link can be made between meditation-induced increase of the HRV and emotion regulation, preliminary results suggest that HRV could be used as both an emotional exposure marker and a meditative state marker. A better understanding of the origin of HRV changes during different

meditation practices may help us understand the mechanisms behind meditation-based emotion regulation.

CONCLUSION

Meditation promotes both physical and mental well-being and contributes to the development of positive emotional traits (K. W. Brown & Ryan, 2003). It is thus important to integrate its active principles in therapies for patients suffering from physical diseases and mental disorders (Bishop et al., 2004). Becoming aware of the fluctuating quality of thoughts, sensations, emotions, and other internal phenomena helps reduce dissociative disorders and the perceptual narrowing that these disorders induce. It also helps reduce alexithymia and emotion avoidance, in which a large number of psychiatric disorders are rooted.

As we have seen, meditation-based interventions such as mindfulness-based stress reduction and mindfulness-based cognitive therapy are already being used in depression relapse prevention programs. These techniques have also been modified and adapted for the treatment of acute disorders such as chronic pain, depression, fibromyalgia, and psoriasis, as well as anxiety, eating, and psychosomatic disorders. In all cases, results have been encouraging and support its use in therapeutic practices (Baer, 2003). In the years to come, we hope to see the development and validation of more meditation protocols adapted to specific disorders.

In the case of eating disorders, the disorder can sometimes be simplified and regarded as resulting from a traumatic emotional experience. Under genetic predisposition and in the context of an adverse social or familial environment, eating disorders foster complete avoidance of negative emotions. Thus, as current negative emotions are instinctively avoided due to early traumatic experiences, eating crises appear to be a preferred mode of emotional shunning. Emotional dissociative disorder and binge eating disorder appear to have identical functions: to suppress the natural emotional process (feeling, labeling, accepting; Hallings-Pott, Waller, Watson, & Scragg, 2005). HRV during MBEE session turns out to be an excellent index of emotion regulation capacity, which is the capacity to feel, label, and accept emotions. The combination of high levels of respiratory sinusual arrhythmia achieved during meditation, enhanced emotional regulation, and the use of more suitable coping strategies has proved useful for weight loss (Fabes & Eisenberg, 1997).

The diverse effects of meditation on the body and cognitive and affective processes are beginning to be

understood, and these techniques are now used in clinical settings for patients suffering from emotional and attentional disorders. The wide range of observable effects of attentional training during meditation allows us to study the multiple connections between the mind, brain, and body. Such connections are increasingly being acknowledged, and their investigation offers new pioneering approaches both in clinical practices and in fundamental cognitive neuroscience research.

An eHealth Approach to the Management of Chronic Sleep Disorders

Carl Stepnowsky
Maxime Bonjean

SLEEP DISORDERS ARE A PUBLIC HEALTH PROBLEM

An estimated 70 million people in the United States suffer from sleep problems, and more than half of them have a chronic sleep disorder (National Center on Sleep Disorders Research, 2003). Sleep disorders have major societal impacts. According to the National Highway Traffic and Safety Administration, 100,000 accidents and 1,500 traffic fatalities per year are related to drowsy driving (NCSDR/NHTSA Expert Panel on Driver Fatigue and Sleepiness, 1998). Nearly two-thirds of older Americans have sleep difficulties, and the prevalence of sleep problems will increase as the older adult population increases (National Sleep Foundation, 2003). Each year, sleep disorders, sleep deprivation, and excessive daytime sleepiness add approximately \$16 billion to the cost of health care in the United States, and result is \$50–\$100 billion (in 1995 dollars) annually in lost productivity (National Commission on Sleep Disorders Research, 1992). One of the key research recommendations put forth by the 2003 National Sleep Disorders Research Plan is that we must develop a better under-

standing of sleep disorders treatments, including treatment adherence, in order to inform evidence-based guidelines for the improved management of sleep disorders (National Center on Sleep Disorders Research, 2003). There are concerns that sleep disorder treatment recommendations are difficult to follow, which can contribute to poor treatment outcomes and missed opportunities to prevent the progression of sleep problems. The four most commonly diagnosed sleep problems are sleep-related breathing disorders, insomnia-related symptoms, narcolepsy, and periodic limb movements in sleep.

The goal of this chapter is to describe the components of an integrative, interdisciplinary model for the diagnosis and treatment for several distinct chronic sleep disorders. The chapter will provide justification for viewing certain sleep disorders as chronic medical conditions, introduce and describe health information technology generally and eHealth specifically, discuss patient-centered collaborative care, and finally integrate these topics and demonstrate how sleep disorder management may be improved by the proposed interdisciplinary model. Because it accounts for more than 75%

of all diagnoses in U.S. sleep clinics, an emphasis will be placed on sleep-related breathing disorders.¹

ACUTE VERSUS CHRONIC ILLNESS MODELS AND SLEEP DISORDERS

The acute illness model and the chronic illness model emphasize different factors in the conceptualization of disease (Holman & Lorig, 1992). Acute illness is characterized by abrupt or rapid onset, limited duration, a single cause (usually), commonly accurate diagnosis and prognosis, and a high cure rate. In contrast, chronic illness is characterized by gradual onset, lengthy or indefinite duration, multivariate causation (which can change over time), and a focus on functional status rather than individual diagnoses; moreover, cure is unlikely and long-term management of symptoms and disease consequences is necessary. Based on these disease characteristics, many sleep disorders can be considered chronic illnesses. Sleep disorders that meet these criteria include sleep-related breathing disorders (in particular, obstructive sleep apnea), narcolepsy, some types of insomnia, and periodic limb movements in sleep.² For example, obstructive sleep apnea has historically been treated as an acute illness, as evidenced by the interventions that were developed in an attempt to cure obstructive sleep apnea, which include surgical alterations to the anatomy of the airway, the implementation of oral appliances to alter the size of the airway, and even medications. A distinctly different treatment, continuous positive airway pressure, has emerged as the most effective form of therapy. As an aid that must be worn throughout the night to provide maximal benefit, continuous positive airway pressure is designed to manage sleep apnea—not cure it. As a chronic illness managed on a night-to-night basis by the affected patient, obstructive sleep apnea is a prime example of a sleep disorder that is best approached not from the acute care model, but from a more contemporary interdisciplinary approach. Likewise, in the sections on insomnia and narcolepsy, we will see that clinical management is best approached from a chronic care model.

1. This chapter complements chapter 6, the focus of which is the nature, regulation, and neurophysiology of sleep, and which provides an in-depth review of specific sleep disorders.

2. Chapter 6 provides more complete information on the full range of sleep disorders.

AN eHEALTH APPROACH TO CHRONIC ILLNESS

The primary approach espoused in this chapter is that chronic sleep disorders may be best approached from a model that incorporates state-of-the-art health information technologies in combination with patient-centered collaborative care. Because of the focus on this textbook, we are not approaching this from a community or societal perspective, but from the perspective of the patient-provider interaction. The chapter is organized into three broad sections: (1) eHealth; (2) patient-centered collaborative care; and (3) application of the combined approach to specific sleep disorders. We now turn to an in-depth discussion of each of these three areas.

INTRODUCTION TO HEALTH INFORMATION TECHNOLOGY AND eHEALTH

What is health information technology? The Agency for Healthcare Research and Quality (2008) broadly defines health information technology as the use of computers and computer programs to store, protect, retrieve, and transfer clinical, administrative, and financial information electronically within health care settings. Key elements of health IT, among others listed by Agency for Healthcare Research and Quality, include (1) confidential online access for consumers to their personal health information, as well as reliable Web-based health information for consumers; (2) electronic, and potentially more efficient, communication between patients and health care providers; (3) electronic prescribing of medications, treatments, and tests, to avoid medical errors; (4) decision support systems to provide clinicians with up-to-the-minute information on best practices and treatment options; and (5) the use of electronic devices like handheld computers to make information available at the point of care. For the purpose of this chapter, we will focus on health IT as it applies to the patient-provider relationship in general. More specifically, we will focus on those technologies that improve quality of medical care offered by providers and obtained by patients (both from within and outside the medical system), from diagnosis to treatment start to treatment maintenance, and inclusive of any health-related educational efforts.

There are many related terms that could be used to describe this area, each of which has different connotations. Various terms used include “medical informatics,”

“telemedicine,” and “eHealth,” among others. It is important to start with the National Library of Medicine’s medical subject headings to understand the current indexing and cataloging of biomedical and health-related information and documents. The reader is referred to a recent article by Pagliari et al. (2005) that graphically maps out the hierarchy of medical subject headings descriptors found under the “medical informatics” descriptor in the medical subject headings tree. The two main subheadings are “medical informatics computing” and “medical informatics applications.” (Please note that the original 2005 article shows three subheadings, but recently the National Library of Medicine moved public health informatics up to the same level as medical informatics.) Because medical informatics computing focuses primarily on systems and hardware, the focus of this section of the chapter falls under medical informatics applications. This area includes “information systems,” “information storage and retrieval,” and “decision-making computer assisted.” Each area then branches into as many as 15 subtopics. Why spend time reviewing to this level of detail? The reason is because no one subtopic captures the cutting-edge activities that are now going in the broad field of medical informatics. We will now take a closer look at a rapidly evolving field that is termed “eHealth.”

A series of articles in the *Journal of Medical Internet Research* has examined the question “What is eHealth?” “eHealth” definitions range from highly vague and diffuse (e.g., “something to do with computers, people, and health”) to highly specific (e.g., the health care industry’s component of business over the Internet). A recent article that attempted to map this field by examining over 36 definitions of eHealth concluded with two relevant definitions (Pagliari et al., 2005, p. 102):

e-Health is the use of emerging information and communications technology, especially the internet, to improve or enable health and healthcare. (Eng, 2001).

e-Health is an emerging field of medical informatics, referring to the organization and delivery of health services and information using the Internet and related technologies. In a broader sense, the term characterizes not only a technical development, but also a new way of working, an attitude, and a commitment for networked, global thinking, to improve health care locally, regionally, and worldwide by using information and communication technology. (Eysenbach, 2001)

This chapter was written in the spirit of this second definition. The term “eHealth” reflects a new paradigm

or way of thinking and approaching health and medicine based on recent advances in health information technologies and the integration of approaches across medicine, psychology, and psychiatry. The emphasis of this chapter will be on the use of state-of-the-art communication technologies to organize and deliver health services, specifically in terms of sleep disorders, and in combination with the latest advances in the chronic illness model.

Please note that the following terms are used interchangeability in the literature and thus in this chapter: “medical informatics,” “health IT,” “telemedicine,” and “eHealth.” It should be mentioned here that another term, “interactive health communication applications,” has been used as well, and much of the original conceptual thinking in this area was started by the Science Panel on Interactive Communication and Health over a decade ago. The panel defined interactive health communication applications as “the interaction of an individual—consumer, patient, caregiver, or professional—with or through an electronic device or communication technology to access or transmit health information or receive guidance and support on a health-related issue” (Eng, Gustafson, Henderson, Jimison, & Patrick, 1999). According to this definition, interactive health communication applications encompass technology-mediated health communication and do not include direct communication such as face-to-face clinician-patient counseling (Eng et al., 1999). The Science Panel on Interactive Communication and Health is no longer active, and their Web site is maintained for historical purposes only. New initiatives to pick up on the earlier work of this panel have since been launched, most notably the e-Health Initiative (<http://www.ehealthinitiative.org>), an independent nonprofit organization whose mission is to drive improvement in the quality, safety, and efficiency of health care through information and IT across multiple stakeholders.

The Reach of eHealth: Who Is Online and What Are They Looking For?

The percentage of adults in the United States that use the Internet is estimated to be 73%, with no difference between men and women (Pew Internet & American Life Project, 2008a). Adult Americans seeking health information on the Web were about 5 times more likely to have broadband access than dial-up as of April 2008 (Horrigian, 2008). This number has increased by 17% in the last year alone. This is important, as eHealth

interventions are increasing in scope and complexity, and many require broadband connections. However, it should be noted that while the United States is ranked second to China in terms of raw number of broadband subscribers, as a percentage of total population it is ranked 16th in the world, with a rate of 1.3 broadband users per 10 people (Vanier, 2008).

The Pew Internet and American Life Project (2008b) 2007 survey of American adults who use the Internet found that 75% of them look for health or medical information. Table 28.1 lists the top five specific health topics for which Internet users search, according to the three most recent Pew surveys. These percentages appear to increase over time.

The rate of use of the Web for prevention is lower than for treatment issues but is nonetheless significant: 51% of respondents with Internet access reported using the Web for information about diet, nutrition, vitamins, or nutritional supplements, and 42% for information about exercise or fitness. Nine percent sought information about smoking cessation. Although 9% of all adult Internet users may seem to be a small proportion, this is more than 10 million individuals and compares favorably with the estimate that 800,000 smokers in the United States call quit hotlines each year for cessation advice (Ossip-Klein & McIntosh, 2003).

Adults living with a disability or chronic disease are less likely than others to go online (51% vs. 73%), but

28.1

Health-Specific Topics Searched Online

HEALTH TOPIC	PERCENT OF INTERNET USERS WHO HAVE SEARCHED FOR INFO ON IT			
	2002	2004	2006	MEAN
Specific disease or medical problem	63	66	64	64
Certain medical treatment or procedure	47	51	51	50
Diet, nutrition, vitamins, or nutritional supplements	44	51	49	48
Exercise or fitness	36	42	44	41
Prescription or over-the-counter drugs	34	40	37	37
A particular doctor or hospital	21	28	29	26
Health insurance	25	31	28	28
Alternative treatments or medicines	28	30	27	28
Depression, anxiety, stress, or mental health issues	21	23	22	22

This table was adapted from three different Pew Internet & American Life project reports dated December 2002 ($N = 1,220$), November 2004 ($N = 537$), and August 2006 ($N = 1,990$). This table shows the top nine health topics that were searched, out of a total of ~17.

once they are online, they are avid health consumers; over 86% of them seek medical information on the Internet (Fox, 2007). These data suggest that it would be worthwhile to target the 49% of patients with a disability or chronic illness to increase their online presence. Also, those with chronic conditions are more likely than other patients to report that their online searches affected their treatment decisions (75% vs. 55%), their interactions with their doctors (69% vs. 52%), and their ability to cope with their condition (57% vs. 36%), as well as their diet and physical activity regimen (56% vs. 42%; Fox, 2007). There are less positive data to report. While patients with chronic conditions do have positive experiences with their online health searches, 30% said they felt overwhelmed by the amount of information they found online and 31% said they felt frustrated by the lack of information or their inability to find what they were looking for. These last two points speak to the need for Web sites to better understand what information health information seekers are looking for, and the need to organize and display that information in a user-friendly manner.

To appreciate the reach of patients who are online, one cannot dismiss what has been termed the “zone of influence” on an “e-patient” (i.e., a patient who regularly accesses the Internet for medical information; Ferguson, 2007). E-patients research medical information on the Web not just for themselves, but for their children, spouses, and other loved ones. One estimate suggests that every 4 e-patients have medical influence over approximately 3 other individuals. Stated another way, if it is estimated that approximately 93 million Americans access the Internet to help them make medical decisions, they affect the medical decisions of nearly 73 million other Americans. Regardless of the accuracy of the number estimates, the main point is that the potential reach of patients who access the Internet for medical information should not be underestimated.

A new report classified patients according to their level of “patient activation” (Hibbard & Cunningham, 2008). Patient activation refers to a person’s ability to manage his or her health and health care and is comprised of four levels: least activated, activated, highly activated, and most activated (Hibbard, Stockard, Mahoney, & Tusler, 2004). The report found that 41% of the population is highly activated, which means that they have adopted many of the behaviors necessary to support their health and health care, but they may not be able to maintain them in the face of stressors. Patients who actively seek information online may be

considered to fall in one of the higher levels of patient activation. Research is currently being conducted to better characterize patients who actively seek out information about their health conditions and then act on that information.

Theoretical Underpinnings of eHealth

It is important to recognize at the outset that the eHealth approach is best viewed as one tool available to health care providers that can potentially help them to improve the quality of health service delivery. New tools or approaches by themselves cannot be the solution but must be considered within the larger context of health care delivery. There exists an evolving body of research on how best to approach patients with chronic medical illnesses, and how best to organize and deliver their care. We believe that a model that keeps these areas distinct and brings them together in an interdisciplinary, collaborative way is likely the best approach for the management of chronic sleep disorders.

Recent articles have examined the theoretical underpinnings of eHealth (Hartvigsen et al., 2007; Whitten, Johannessen, Soerensen, Gammon, & Mackert, 2007). One study found that 3% of published studies on eHealth in 1999, and 7% in 2005, were explicitly on theory, and that the number of theories used in these studies was quite varied (Gammon, Johannessen, Soerensen, Wynn, & Whitten, 2008). The authors distinguished between recognized categories of theories as well as “lone ranger” theories, which were defined as not fitting within one of the categories. Categories of theories found in this study were diffusion, technology acceptance, health behavior, science and technology studies, and economics. The study found that the number of lone ranger theories outnumbered the recognized theories and concluded that because telemedicine or eHealth studies utilizes such a wide variety of theoretical underpinnings, that there is no commonly accepted approach that could be considered unique to telemedicine or eHealth studies.

One of the few comprehensive models for how eHealth interventions might work was proposed in a Cochrane review of interactive health communication applications for people with chronic diseases (Murray, Burns, See, Lai, & Nazareth, 2005). Figure 28.1 shows their postulated pathway or mechanism of eHealth interventions, which was based on the health psychology/behavioral medicine literature, self-management literature, and specific interactive health communication applications/eHealth interventions. The authors

suggest that these interventions work by combining health-related information with an additional service (peer support, decision support, or behavior change support) to allow for internalization and interpretation of the information by the patient. This in turn leads to changes in self-efficacy, motivation for improved health or health behaviors, and/or affective parameters. The combination of enhanced self-efficacy with motivation and knowledge enables users to change their health behaviors, leading in turn to changes in clinical outcomes. The focus of the Cochrane review was to test this hypothesized pathway of action and provides a general model against which other eHealth interventions can be assessed. The results of this Cochrane review are discussed below.

eHealth Methodology: How Are eHealth Interventions Delivered?

In the early days of the Internet, the focus was on searching for information. In the health arena, many organizations focused on putting together vast amounts of health-related information for patients to find and read. However, use of the Internet as simply a clearinghouse for information neglects its very power and advantage. To understand what is possible for medical service delivery via the Internet today, we have to understand what interventions are possible via the Internet. And to understand that, we have to understand the various ways the user can interact with the

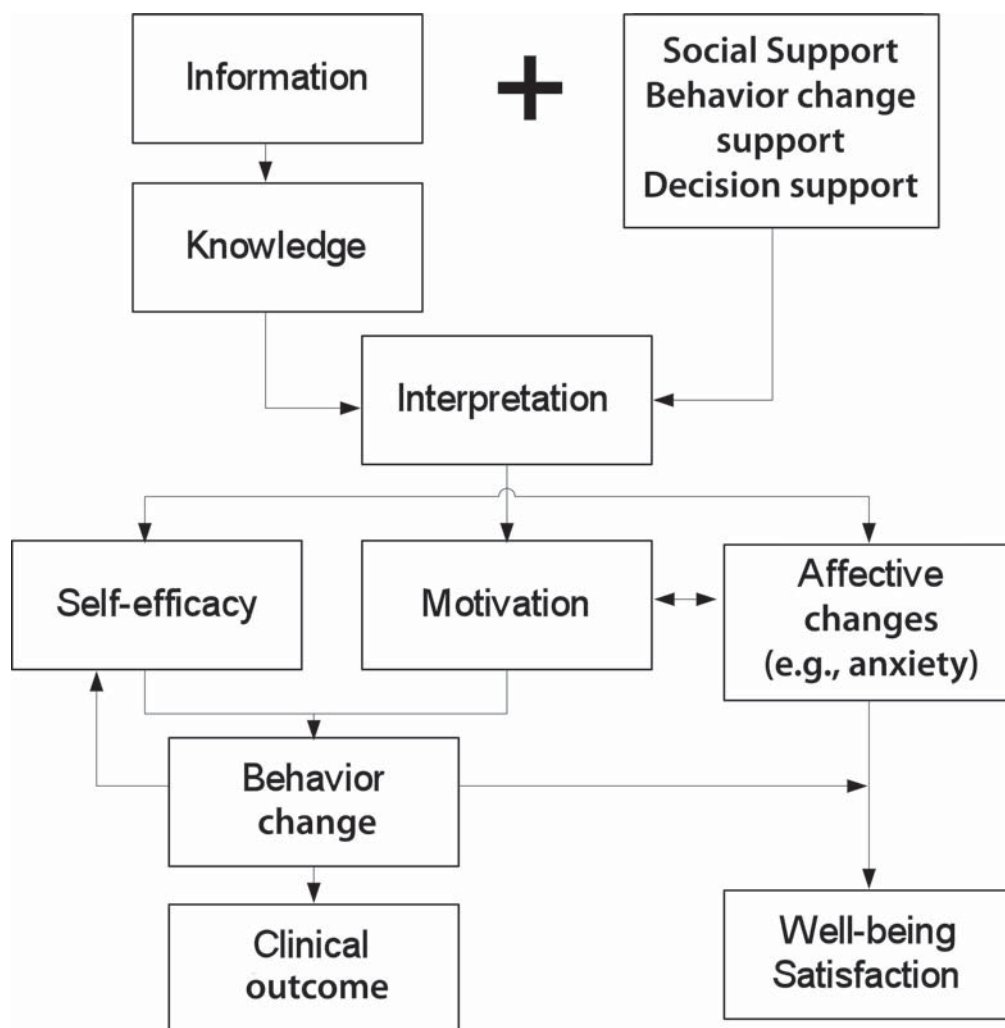

Figure 28.1 Postulated mechanisms of eHealth interventions.

Internet. A recent review of eHealth methods for delivering health-related and behavioral interventions classified four different ways a user can interact with the Internet: (1) user navigation; (2) collaborative filtering; (3) expert systems; and (4) human-to-human interaction (Streicher, 2007).

- (1) *User Navigation*. This method of interacting with the Internet can best be described as having a vast library at your fingertips. One uses the Internet just as one might enter a library, seek information, and read that information. Of course, just as in a library, the information seeker may find information, but he or she may not know the quality of the information or understand the comprehensiveness (or lack thereof) of the search. The prototypical example is entering a medical term or the name of a procedure into Google and examining the hits.
- (2) *Collaborative Filtering*. This method of interacting with the Internet can best be described as finding out what others like you are doing. We all engage in this sort of filtering in our everyday lives when friends or relatives say something like "If you like restaurant A, you will love restaurant B." On the Internet, a Web site can be programmed to assess a few key variables and to return a recommended diet or exercise regimen. For disease-specific issues, this could take on other forms as well. One recently developed example is a Web site called organized wisdom (<http://www.organizedwisdom.com>). It employs medical experts who are familiar with the various Web sites in their area of practice and put together what they term "wisdom cards," which are lists of key Web sites that are topically organized. So if a patient did a search for the common cold, the "wisdom card" would be organized by about 12 key topics, with no more than five links per topic, such as "great resources," "What is the common cold?" "What are symptoms of the common cold?" In this way, the patient is able to obtain "filtered" Web sites and has theoretically engaged in a more targeted search and can more easily find the information he or she is seeking.
- (3) *Expert Systems*. This method of interacting with the Internet is the one that approximates a counseling experience but does not involve the face-to-face interaction. In a sense, the Web site is programmed or automated to do a portion of what a counselor might do. In other words, the Web site is programmed with the expert's assessment, decision rules, and feedback strategies. These types of systems are the most studied of the four patient-Internet types of interactions. The key aspects of these systems are the algorithm that uses assessment data to generate tailored messages and feedback that is clear and understandable to the patient. The next section will focus on the quality of these systems and how efficacious they are for promoting behavioral changes and improving clinical outcomes.

It is important to note that expert systems have the advantage of large reach and low cost. A key question concerns the lack of human contact, especially the lack of empathy and other characteristics that help to forge a therapeutic alliance. One study successfully incorporated what was termed "relational behaviors" into the expert system (Bickmore, Gruber, & Picard, 2005). Relational behaviors refer to those skills that are associated with building and maintaining good working relationships over multiple interactions. Examples of those skills include empathy, social dialogue, and nonverbal immediacy, among others. This particular study showed that a Web site designed with relational behaviors resulted in higher levels of working alliance and desire to continue working with the Web site.

- (4) *Human-to-Human Interactions*. This method can best be characterized as an online channel or medium for social support that connects patients to each other electronically. These can take the form of blogs, chat rooms, or forums. They have the advantage of being anonymous and available 24 hours a day, 7 days a week. Of course, with recent advances in technology such as Skype (<http://www.skype.com>), it is now rather straightforward and inexpensive to connect via videoconferencing. Research shows that online support groups allow patients a convenient way to provide and receive informational and emotional support. While the literature is evolving, one review of 10 studies found that online cancer support group patients were better able to cope with their disease (Klemm, Bunnell, Cullen, Soneji, Gibbons, & Holecek, 2003). Another type of human-to-human interaction on the Internet is with an online therapist. One study of an Internet weight-loss program found that the addition of an online therapist to the program had a significant impact on 12-month weight loss (Tate, Jackvony, & Wing, 2003). While an online therapeutic interaction can benefit both patient and therapist, there are significant issues about this type of relationship, and what can or cannot work for a particular condition or issue will need to be examined.

So which interactive strategy *should* be used? One exciting area of future research will be the tailoring of strategies to specific characteristics, either of the patient, the medical condition, or others. Our view of the human-to-human interactions is to take a stepped approach—provide as much information, content, and interactive features as possible, and at the moment either the therapist or patient believes a phone call or face-to-face visit is needed, then that next step is taken. As we begin to more fully describe our eHealth approach for chronic sleep disorders, we will be reviewing the literature and focusing on incorporating aspects from all four methods. Given the limited research to date, we will not discuss the role of tailoring across interactive technologies.

Are eHealth Interventions Efficacious?

In a large Cochrane review study, eHealth interventions were found to have largely positive effects on users, in that users tended to become more knowledgeable, felt better socially supported, and may have improved behavioral and clinical outcomes compared to non-users (Murray et al., 2005). The standardized mean differences for these three areas was 0.46 (95% CI [0.22, 0.69]), 0.35 (95% CI: 0.18, 0.52), and 0.18 (95% CI [0.01, 0.35]), respectively. The review also found a positive effect on self-efficacy, 0.24 (95% CI [0.00, 0.48]), and behavioral outcomes, 0.20 (95% CI [0.01, 0.40]).

Other systematic reviews on health information technological approaches to medical care have been performed. One found that health IT improves quality and efficiency of medical care (Chaudhry et al., 2006). However, the studies found were limited in number and were performed by a small number of institutions—whether and how other institutions can achieve similar benefits, and at what cost, should be the subject of future research, per this review. Two other systematic reviews were based on disease condition. Pare, Jaana, and Sicotte (2007) studied four conditions (pulmonary, diabetes, cardiac, and hypertension) and concluded that home telemonitoring of these four conditions is a promising patient management approach that produces accurate and reliable data, empowers patients, influences their attitudes and behaviors, and potentially improves their medical conditions. While the Pare review was inconclusive in terms of telemonitoring's effect on clinical outcomes, Dellifraigne and Dansky (2008) performed a meta-analysis that found that telehealth interventions had a moderate, positive, and significant effect on clinical outcomes.

Limitations of eHealth

Potential limitations of eHealth interventions need to be acknowledged. These include the risk of loss of privacy, the potential to reinforce the problems the intervention was designed to help, and the fact that while health IT interventions may help overcome issues of time, mobility, and geography, they may never truly substitute for the quality of care that can be provided during a face-to-face visit. In one of the few studies of its kind, Nijland, van Gemert-Pijnen, Boer, Steehouder, and Seydel (2008) studied the problems encountered by patients who undertook an eHealth self-care intervention. They found that user friendliness was a key issue because patients spent less time on and received less benefit from the intervention when they were frustrated by the difficulty they experienced navigating the Web site. Patients wanted tailored feedback specific to their situation, but in many cases they felt they did not receive tailored care (it may have been that the level of tailoring did not meet their expectations). The authors concluded that the designers of eHealth interventions should think about how to deliver health care with the aid of technology and not doing so may significantly limit the effect of the intervention. They added that a focus on interactivity (i.e., between patient and technology) was critical to helping patients in their self-care.

PATIENT-CENTERED CARE FOR CHRONIC ILLNESS

Per the Institute of Medicine, an essential component of quality medical care is patient centeredness (Institute of Medicine Committee on Quality of Health Care in America, 2001), a component that historically has been both underappreciated and underutilized, despite being described as early as 1969 as by Balint (1969). The Institute of Medicine described six specific aims for improving health care and 10 design rules for retooling health care. One of the six aims was on patient centeredness, which refers to the patient's experience of illness and health care and on the systems that work, or fail to work, to meet individual patients' needs. Table 28.2 lists the 10 redesign rules, 7 of which are directly related to the critical role of patient-centered care. These are the patient as a source of control of that care, shared knowledge and the free flow of information, care based on a continuous healing relationship, anticipation of needs, and customization of care based on patient needs and values.

28.2

Ten Rules to Redesign and Improve Health Care

HEALTH CARE REDESIGN RULE	PATIENT CENTERED?
(1) Care based on continuous healing relationship	Yes
(2) Customization based on patient needs and values	Yes
(3) The patient as a source of control	Yes
(4) Shared knowledge and the free flow of information	Yes
(5) Evidence-based decision making	Yes
(6) Safety as a system property	No
(7) The need for transparency	No
(8) Anticipation of needs	Yes
(9) Continuous decrease in waste	No
(10) Cooperation among clinicians	Yes

At its core, patient centeredness involves both (1) the patient's experience of, and contribution to, medical care and (2) the presence of an effective partnership between clinician and patient (i.e., the clinician as a "collaborator"). This partnership is the product of a relationship in which the clinician's recommendations are informed by an understanding of the individual patient's needs and context in order to improve the patient's ability to act on the information provided. Furthermore, an effective clinician-patient partnership is characterized by informed, shared decision making, and development of patient knowledge and skills needed for self-management of chronic conditions (Davis, Schoenbaum, & Audet, 2005). In no small part what is being described can be considered "collaborative management" or "collaborative care."

Collaborative management was defined a decade ago as "care that strengthens and supports self-care in chronic illness while assuring that effective medical, preventive, and health maintenance interventions take place" (von Korff, Gruman, Schaefer, Curry, & Wagner, 1997, p. 1098). Von Korff and colleagues suggested that the following essential elements are common across

chronic illness care and were developed based on behavioral principles of behavior changes and empirical evidence about effective chronic illness care: (1) collaborative definition of problems (patient-defined problems are identified along with medical problems diagnosed by physicians); (2) targeting, goal setting, and planning (patients and providers focus on a specific problem, set realistic objectives, and develop an action plan for attaining those objectives in the context of patient preferences and readiness); (3) creation of a continuum of self-management training and support services (patients have access to services that teach skills necessary to carry out medical regimens, guide health behavior changes, and provide emotional support); and (4) active and sustained follow-up (patients are contacted at specified intervals to monitor health status, identify potential complications, and check and reinforce progress in implementing the care plan).

Patient-Centered Collaborative Care

Our preference for terminology describing this relationship between patient and provider is "patient-centered

collaborative care.” The spirit of this phrase can be captured in large part by this paraphrased statement from an article by Moore and Wasson (2006): “Patients receive the care they need at the time and in the way that they need it” (p. 196). One of the most popular models in the literature is the chronic care model developed by Ed Wagner and colleagues (2005) at the MacColl Institute. The model takes a broad perspective by identifying six essential elements of a health care system that encourage high-quality chronic disease care. Figure 28.2 provides a graphic representation. These elements are proposed to result in, or set the stage for, for productive interactions between an informed and activated patient and a prepared and proactive care team. We view these interactions as the fundamental unit of our idea of patient-centered collaborative care.

The six elements are (1) the community, (2) the health system, (3) self-management support, (4) delivery system design, (5) decision support, and (6) clinical information systems. Evidence-based change concepts under each element, in combination, foster productive interactions between informed patients who take an active part in their care and providers with resources and expertise.

The reader is encouraged to look to this model to better understand the larger factors involved, especially because these factors are relevant when one is trying to establish chronic care programs in medium to large health care systems. For the purposes of this chapter, we will not focus on the community or health system elements.

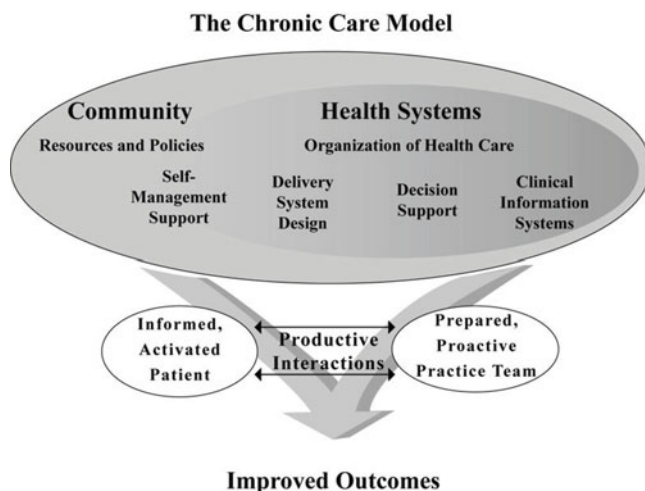

Figure 28.2 The chronic care model and its essential elements.

There is much research to support a patient-centered approach to care: patients who are involved with their care decisions and management have better outcomes than those who are not (Greenfield, Kaplan, & Ware, 1985; Greenfield, Kaplan, Ware, Yano, & Frank, 1988; E. H. Wagner et al., 2001; T. H. Wagner, Hibbard, Greenlick, & Kunkel, 2001). Patient self-management, particularly for chronic conditions, has been shown to be associated with improvements in health status and decreased utilization of services (Lorig et al., 1999; Stepnowsky, Palau, Gifford, Marler, & Ancoli-Israel, 2006).

eHEALTH AND PATIENT-CENTERED CARE

eHealth applications can help build a patient-centered health care system in which patients share information and control with (i.e., in collaboration) their providers. Early experience confirms that when patients are given the chance to bridge the information gap between themselves, their health data, and their health care providers, many enthusiastically take a more active role (Working Group on Policies for Electronic Information Sharing Between Doctors and Patients, 2004). A recent review of 24 randomized controlled trials of interactive health communication applications for patients with chronic illnesses found preliminary evidence that the applications improved behavioral and clinical outcomes, as well as medical knowledge, social support, and perceived self-efficacy. For example, such an approach has had positive effect on health outcomes for patients with low back pain (Lorig, Laurent, Deyo, Marnell, Minor, & Ritter, 2002) and helped improve smoking cessation rates (Lenert et al., 2003). We believe there is strong evidence that health IT can promote patient-centered care for sleep disorder patients in terms of fostering the productive interactions between patients and providers. In fact, because sleep disorders are unique in that they take place while a person is asleep, and therefore unaware of the problem, education and understanding of the illness and its consequences are critical for laying the groundwork for a successful intervention.

eHealth and Patient-Centered Collaborative Care as Applied to Chronic Sleep Disorders

The term “sleep-related breathing disorders” (SRBD) refers broadly to any breathing disorder that occurs during sleep, including obstructive sleep apnea syndromes

(OSA) and central sleep apnea syndromes (CSA). OSA is divided into adult or pediatric. CSA is subdivided into primary CSA, CSA due to a medical condition, and CSA due to a drug or substance. SRBD also includes the subcategories of sleep-related hypoventilation/hypoxemic syndromes and other sleep-related breathing disorders.

Obstructive Sleep Apnea

OSA is by far the most prevalent SRBD subtype, accounting for an estimated 75% of sleep clinic diagnoses. OSA is a prevalent and serious medical condition characterized by repeated complete or partial obstructions of the upper airway during sleep (apneas and hypopneas, respectively). It is prevalent in 2%–4% of working middle-aged adults (Young, Palta, Dempsey, Skatrud, Weber, & Badr, 1993) and an increased prevalence is seen in the elderly (~24%; Ancoli-Israel, Kripke, Klauber, Mason, Fell, & Kaplan, 1991; Bixler, Vgontzas, Ten Have, Tyson, & Kales, 1998), veterans (~16%; Sharafkhaneh, Richardson, & Hirshkowitz, 2003), and possibly African Americans (Ancoli-Israel, Klauber, Stepnowsky, Estline, Chinn, & Fell, 1995; Redline, Tishler, Hans, Tosteson, Strohl, & Spry, 1997). Obesity is a major risk factor for OSA, as the risk of OSA increases significantly with increased weight (Young et al., 1993). Over 75% of OSA patients are reported to be more than 120% of ideal body weight (Kales et al., 1985). Estimates of health care costs for OSA patients are approximately twice that of matched healthy controls (Kapur et al., 1999). This increased cost of care is directly related to OSA severity and becomes evident several years prior to the diagnosis (Ronald, Delaive, Roos, Manfreda, Bahammam, & Kryger, 1999). OSA is associated with shortened survival (i.e., higher mortality rate) in prospective studies of coronary artery disease patients (Peker, Hedner, Kraiczi, & Loth, 2000) and community-dwelling elderly (Ancoli-Israel et al., 1996), as well as in several large retrospective studies (He, Kryger, Zorick, Conway, & Roth, 1988; Lavie et al., 1995; Partinen, Jamieson, & Guilleminault, 1988).

Medical and Psychosocial Consequences of OSA

OSA is associated with several cardiovascular diseases, most notably hypertension, ischemic heart disease, heart failure, stroke, cardiac arrhythmias, and pulmonary hypertension. Compared to the general population, OSA patients have twice the risk for hypertension, 3 times the risk for ischemic heart disease, and 4 times the risk for cerebrovascular disease (Peppard, Young, Palta, & Ska-

trud, 2000; Strohl & Redline, 1996; Young et al., 1997). The evidence supporting the link between OSA and hypertension is compelling, and OSA is now officially recognized as an identifiable cause of hypertension (Chobanian et al., 2003). Evidence shows that OSA bears a dose-response relationship to hypertension independent of other known risk factors (Bixler et al., 2000; Duran, Esnaola, Rubio, & Iztueta, 2001; Nieto et al., 2000; Palomaki, 1991; Young et al., 1997), the incidence of hypertension in apneic patients is as high as 53% (Shepard, 1992), and OSA is highly likely to be present in drug-resistant hypertension patients (Logan et al., 2001).

Alterations in sleep architecture cause sleep to be nonrestorative, resulting in mildly to severely excessive daytime sleepiness. Excessive daytime sleepiness and/or hypoxia secondary to OSA are associated with a number of neurocognitive, mood, and behavioral consequences, including lowered health-related quality of life (Flemons, 2000; Stepnowsky, Johnson, Dimsdale, & Ancoli-Israel, 2000; Weaver, Laizner et al., 1997), impaired cognitive performance (Beebe, Groesz, Wells, Nichols, & McGee, 2003; Engleman, Kingshott, Wraith, Mackay, Deary, & Douglas, 1999; Kim, Young, Matthews, Weber, Woodward, & Palta, 1997), impaired driving ability (2 to 7 times increased risk of a motor vehicle accident; Engleman, Hirst, & Douglas, 1997; Findley, Fabrizio, Knight, Norcross, LaForte, & Suratt, 1989; Findley, Suratt, & Dinges, 1999), dysphoric mood (Aikens, Caruana-Montaldo, Vanable, Tadimeti, & Mendelson, 1999; Aikens & Mendelson, 1999; Mosko et al., 1989; Reynolds, Kupfer, McEachran, Taska, Sewitch, & Coble, 1984), psychosocial disruption (e.g., more impaired work performance and productivity and higher divorce rates; Grunstein, Stenlof, Hedner, & Sjostrom, 1995), and disrupted sleep and impaired quality of life of spouses of OSA patients (McArdle, Kingshott, Engleman, Mackay, & Douglas, 2001; Parish & Lyng, 2003).

OSA Diagnosis

Polysomnography is the first-line diagnostic approach when OSA is suspected. OSA exists in asymptomatic adults if the Apnea-hypopnea index (AHI) is greater than 15 events per hour, and in symptomatic adults if the AHI is greater than 5 events per hour. During polysomnography, the patient sleeps while connected to a variety of monitoring devices that record physiologic variables, usually up to approximately 17 different channels. Recently, home sleep testing (HST) has been approved for reimbursement. HST uses a limited channel sleep recording system, more on the order of 4–7 channels depending on the system and sleep provider preference. Table 28.3

lists studies on eHealth systems that have been developed for sleep apnea diagnosis and management. The main efforts have focused on reducing the amount of wires associated with polysomnography by adding Bluetooth wireless capabilities to transmit sleep data from the patient to the recording unit on the side of the bed. This has the added benefit of allowing the patient to not have to disconnect at night should he or she need to get out of bed. However, the next development should allow for the remote monitoring of sleep physiological data at a distance (i.e., patient at home, sleep technician at a sleep center). The main problem with home sleep studies is potential data loss, and remote data monitoring could allow for reduction of data loss, which has the added benefits of reducing patient burden for multiple nights of sleep recording and reducing the amount of unnecessary deployment of the sleep recording systems.

OSA Treatment: Continuous Positive Airway Therapy

The goal of OSA treatment is the elimination of breathing events and snoring, maintenance of high blood oxygen levels, and improvement of symptoms. Nasal continuous positive airway pressure (CPAP) is the treatment of choice for this condition (Loube, Gay, Strohl, Pack, White, & Collop, 1999; Sullivan, Issa, Berthon-Jones, & Eves, 1981). CPAP provides positive pressure via the nasal passages and/or oral airway, creating a pneumatic “splint” to keep the airway open during inspiration.

Meta-analytic reports of numerous randomized controlled trials show that CPAP improves both objectively and subjectively measured daytime sleepiness (Patel, White, Malhotra, Stanchina, & Ayas, 2003) as well as health-related quality of life (Wright, Johns, Watt, Melville, & Sheldon, 1997). CPAP has been shown to normalize sleep architecture (McArdle et al., 2001) and reduce blood pressure (Pepperell et al., 2002). Most importantly, from a dose-response relationship perspective, CPAP is related to improved outcomes in a near-linear relationship; that is, that the more that CPAP is used, the better the outcomes are (Stepnowsky & Dimsdale, 2002; Stepnowsky & Moore, 2003; Weaver et al., 2007). While other medical treatments for OSA exist, our focus will be on the gold-standard treatment of CPAP because of its documented efficacy. We now turn to an in-depth examination of CPAP treatment adherence.

CPAP Treatment Adherence

In the case of OSA treatment and management, the need for close patient monitoring using objective data is now considered standard practice per the 2006 American Academy of Sleep Medicine Practice Parameter report

and review (Kushida, Littner, et al., 2006; Kushida, Morgenthaler et al., 2006). The main reason is that, despite the standard CPAP prescription to use CPAP whenever one is asleep (including naps), CPAP adherence levels are universally low, with estimates in the suboptimal range of 3–5 hours per night (Collard, Pieters, Aubert, Delguste, & Rodenstein, 1997; Stepnowsky & Moore, 2003). To illustrate, a seminal study of CPAP adherence defined minimally acceptable and optimal use of CPAP as at least 4 and 7 hours, respectively, on at least 5 out of 7 nights per week (Kribbs et al., 1993). By those criteria, 46% of that study’s sample could be categorized as minimal use and only 6% as optimal use, with an average nightly use for the sample of 5.3 hours. While there is modest evidence that education and counseling can improve CPAP adherence (Aloia, Arnedt, Riggs, Hecht, & Borrelli, 2004; DeMolles, Sparrow, Gottlieb, & Friedman, 2004; Engleman & Wild, 2003; Hoy, Vennelle, Kingshott, Engleman, & Douglas, 1999; Means, Edinger, & Husain, 2004), the various interventions tried to date have produced mixed and mostly nonsignificant results (Haniffa, Lasserson, & Smith, 2004), at least in part as a result of insufficiently powered research designs with too small sample sizes for adherence data to be meaningfully evaluated. Consistent research findings are that CPAP patients tend to abandon the therapy early in the treatment initialization process, and non-adherent users have proved identifiable as early as the fourth day of treatment (Weaver, Kribbs, et al., 1997). Consequently, there is general consensus within the field that the earlier patients are closely monitored and supported, before undesirable patterns of CPAP use are established, the more likely an intervention designed to improve and sustain adherence will be successful (Chervin, Theut, Bassetti, & Aldrich, 1997; Collard et al., 1997; Gordon & Sanders, 2005; Malhotra, Ayas, & Epstein, 2000). This conclusion is remarkably consistent with the chronic care model approach.

The central unifying themes regarding OSA-CPAP patients are that (1) patients *want* to and *can* engage in the self-care necessary to make CPAP work for them and (2) health IT has the capability of helping to close the treatment data feedback loop and promoting a patient-centered collaborative management approach to CPAP management for OSA patients.

Rationale for Chronic Care Approach for Treating OSA

The acute illness model and the chronic illness model emphasize different factors in the conceptualization of disease (Holman & Lorig, 1992). Acute illness is characterized by abrupt or rapid onset, limited duration, a

single cause (usually), commonly accurate diagnosis and prognosis, and a high cure rate. In contrast, chronic illness is characterized by gradual onset, lengthy or indefinite duration, multivariate causation (which can change over time), and a focus on functional status rather than individual diagnoses; moreover, cure is unlikely and long-term management of symptoms and disease consequences is necessary. Based on these disease characteristics, OSA is a chronic illness. Historically, OSA has been treated as an acute illness. Interventions developed in an attempt *cure* OSA include alterations to the anatomy of the airway through surgery (Li, 2005), oral appliances (Bailey, 2005), and even medications (Qureshi & Lee-Chiong, 2005).

CPAP has emerged as the most effective form of therapy, but it is unlike previous “curative” treatments. An aid that must be worn throughout each night in order to provide maximal benefit, CPAP is designed to manage apnea over time, not to cure it. As a chronic illness managed on a night-to-night basis by the affected patient, OSA is an excellent target for behavioral intervention to improve long-term self-management. The question then becomes, what is the best approach? We believe one strong answer is the patient-centered collaborative care approach combined with health IT.

One of the essential components of the chronic care model is patient self-management. Self-management for chronic disease can be defined broadly as a systematic intervention that is targeted toward patients with chronic disease to help them participate actively in both self-monitoring (of symptoms or physiologic processes) and decision making (managing the disease or its impact based on self-monitoring; Shekelle, 2003). Chronic disease self-management programs, in collaboration with and under the care of providers, focus on helping to teach the patient to identify problems, generate solutions, choose and implement a solution, and then track progress. Creating tailored interventions specific to patient needs is an effective method for promoting behavior change (Strecher, 1999; Strecher, Wang, Derry, Wildenhaus, & Johnson, 2002). Self-management programs are thought of as the next generation of tailoring, known as self-tailoring (Lorig & Holman, 2003). Self-tailoring requires the individual to learn the principles of making specific behavior changes and self-management skills. However, central to this approach is accurate feedback regarding treatment efficacy. Typically this is the missing link because providers and patients may have subjective reports of treatment efficacy and progress, but rarely do they have more objective data with which to work. Figure 28.3 shows how telemonitoring allows for the feedback of objective data via providers to pa-

tients in a timelier and more frequent way. Involved are social-cognitive theory variables, which may be one of the mechanisms that allow understanding of behavioral change (in this case, the behavior = using CPAP). Treatment adherence can be established earlier in the treatment process, and telemonitoring allows for early and frequent intervention with the potential to both reduce the rate of CPAP rejecters and increase the rate of adherence in those who decide to use the therapy.

Why implement a self-management program for sleep apnea patients? There are a number of reasons why a self-management approach might be appropriate for OSA patients who are prescribed CPAP therapy. First, qualitative research has shown that OSA affects multiple aspects of an individual’s health-related quality of life, including (1) managing OSA symptoms, CPAP side effects, and weight loss (e.g., disease, treatment, and health management); (2) maintaining work performance, social contacts, and family relationships (e.g., role management); and (3) dealing with symptoms of depression and anxiety (e.g., emotional management) (Flemons, 2000; Flemons & Reimer, 1998; Veale, Poussin, Benes, Pepin, & Levy, 2002; Weaver, Laizner, et al., 1997). The similarities between the problems reported by OSA patients and the content areas of the self-management approach are remarkable. Using qualitative methods such as focus groups and discourse analysis, these studies repeatedly show that one of the core issues with which the sleep apnea patient must contend is problem solving (i.e., how best to manage problems within each of the content areas; Veale et al., 2002). Indeed, a recently proposed model of self-management behavior for chronic illness has as its core component problem solving (Hill-Briggs, 2003). It is reasonable to assert that sleep apnea patients may be able to benefit considerably from a self-management approach to CPAP management.

Second, published behavioral intervention studies have focused on CPAP adherence as the primary outcome of interest, and patient outcomes as secondary. The conceptual model upon which the Sleep Apnea Self-Management Program (SASMP) is based is drawn from both the self-management and OSA/CPAP literature. Studies on the effects of self-management interventions suggest that increased self-efficacy—that is, confidence in one’s ability to engage in behavior (Bandura, 1997)—may be as important as the actual engagement in prescribed health behaviors, including treatment adherence, and in improving chronic illness health outcomes (Lorig & Gonzalez, 1992; Lenker, Lorig, & Gallagher, 1984; Lorig, Seleznick, Lubeck, Ung, Chastain, & Holman, 1989). The OSA treatment literature suggests that increased

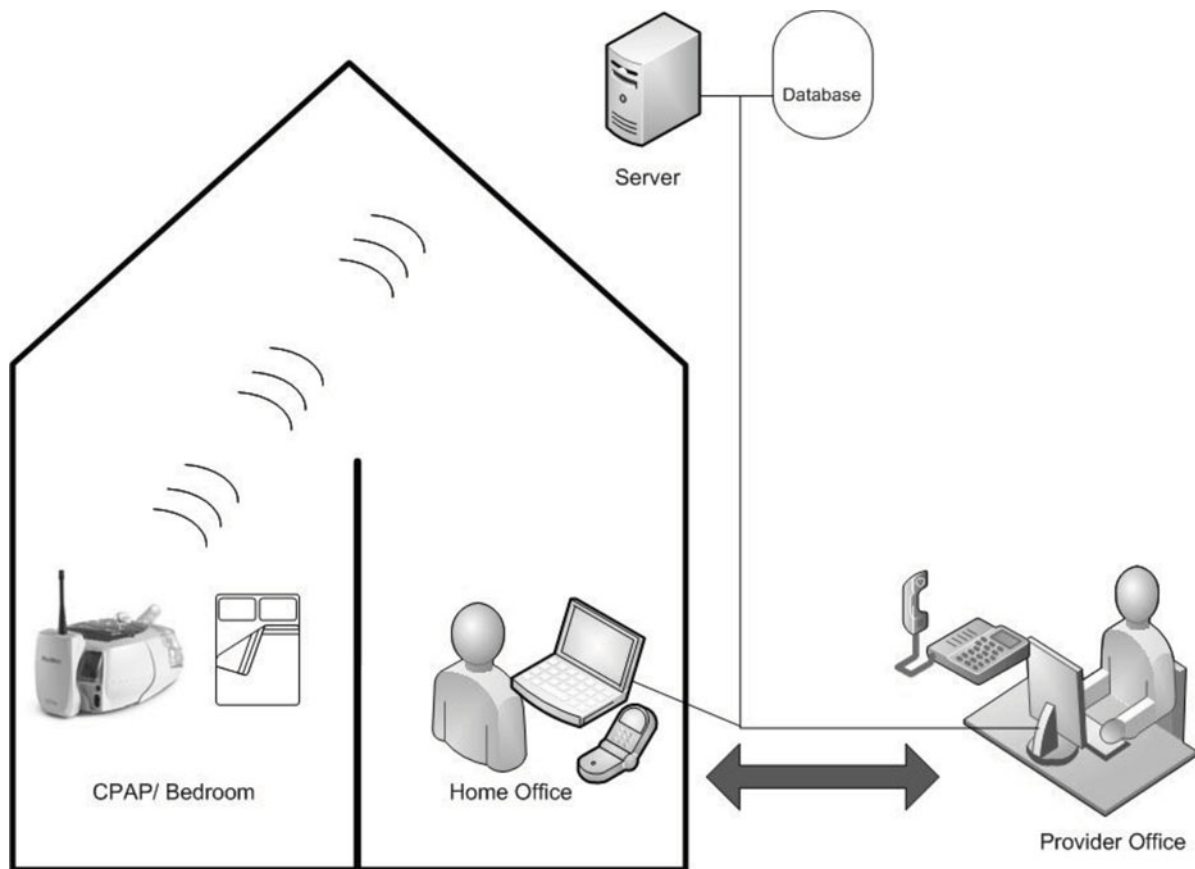

Figure 28.3 Wireless model.

use of CPAP is significantly associated with reductions in OSA symptoms and improvements in health-related quality of life (Engleman & Wild, 2003; Stepnowsky & Dimsdale, 2002; Stepnowsky & Moore, 2003; Stradling & Davies, 2000; Weaver et al., 2003). Specifically, our model proposes that SASMP can improve CPAP adherence, and that the mediating effects may be through social cognitive variables, such as self-efficacy. Figure 28.1 graphically represents the model and is adapted from a 2003 evidence-based Rand report on self-management (Shekelle, 2003). The SASMP seeks primarily to improve patient outcomes through the use of a theory-driven intervention that allows for empirical testing of putative mediating variables. Therefore, testing of the intervention and its components can be performed in a rational, programmatic way and can lead to support for or modification of the theory upon which the SASMP is based.

Third, self-management programs are conducted in a group format and can utilize lay leaders, thereby potentially augmenting preexisting clinical and support

services. Limited health care resources often prevent patients from receiving optimal follow-up care. Patients can spend maximal time and effort in the self-management group, learning new skills and building confidence to manage their condition, time that health care professionals cannot efficiently spend with patients in typical clinical settings. In a sense, the self-management approach attempts to cost-efficiently intensify clinical support and follow-up for sleep apnea patients.

To summarize, the self-management approach is well suited as a method for helping to introduce CPAP therapy to the OSA patient and is consistent with the chronic care model. How this approach can be combined with the more objective CPAP adherence and efficacy data is the subject of the next section.

Wireless CPAP Study

One study on the efficacy of wireless telemonitoring of CPAP patients has been completed (Stepnowsky, Palau,

Marler, & Gifford, 2007). This was a randomized, controlled study conducted with patients who had never before used CPAP treatment and utilized a wireless device manufactured by ResMed Corporation. For wireless telemonitoring of CPAP adherence, ResMed developed the Restraxx Data Center, composed of the Restraxx wireless module, which affixes to and transmits data from the CPAP flow generator, and the server/database, which houses the data and, being fully HIPAA compliant, restricts access to authorized health care professionals. The specific aims of the pilot were to (1) compare the amount of nightly CPAP use and CPAP efficacy for patients receiving the wireless data monitoring intervention (the “enhanced” clinical care group) and the control patients receiving usual clinical care; (2) evaluate the accuracy of the data obtained via wireless monitoring compared to the data recorded on the flow generator unit (nightly use data and flow generator efficacy data), that is, test the reliability and validity of the Lankford (2004) results; and (3) quantitatively assess patient and provider (physician and pulmonary clinic staff) satisfaction with the monitoring capabilities of the wireless system, as well as the advantages and disadvantages of wireless monitoring and its potential incorporation into routine clinical management.

Across 30 patients, there were 2,270 nights available for the accuracy comparison between adherence data that was obtained wirelessly versus manually downloaded directly from CPAP unit. There were wireless data transmission failures on 182 days, or 8% of the total nights, owing to user error (typically due to patients’ failure to power on the CPAP units). Overall, 2,088 nights were available for comparison (2,270–182), and an analysis found 100% accuracy between data obtained wirelessly versus data manually downloaded (confirming the Lankford results).

Adherence in the enhanced clinical care group was 4.1 ± 2.0 (mean \pm SD) hours of use per night versus 2.8 ± 2.3 hours per night in the control group. This is equivalent to an effect size of 0.65 and represents a 46% higher level of CPAP adherence relative to usual care. The amount of mask leak was lower in the enhanced clinical care group, with a 95th percentile mask leak equal to 0.33 ± 0.20 l/sec in the enhanced clinical care group versus 0.51 ± 0.54 l/sec in the control group. One treatment goal is to maintain mask leak levels below 0.4 l/sec in order to sustain prescribed pressure level (high leak can reduce effective pressure, thereby reducing treatment efficacy). Presumably, lower mask leakage in enhanced clinical care group might be a result of early corrective action by clinical staff. Patient satisfaction with telemonitoring was very high. The enhanced clinical care group

rated their overall satisfaction with care at 4.8 on average (where 1 = “poor”; 5 = “excellent”), their likelihood to continue to use CPAP at 4.5 on average (where 1 = “not likely”; 5 = “highly likely”), and their concern about being monitored wirelessly at 1.1 on average (where 1 = “not concerned”; 5 = “highly concerned”). It should be noted that the Web site was only accessed by the CPAP therapist, not the patients themselves.

These findings regarding the efficacy of viewing and acting on CPAP data sent wirelessly to a Web site for CPAP provider review, combined with previous findings on the patient self-management approach to CPAP management (Stepnowsky, Palau, Gifford, & Ancoli-Israel, 2007), provide the rationale for an approach that uses health IT to promote patient-centered collaborative sleep apnea care.

Example of a Health IT Application: Development of an Interactive OSA/CPAP Web Site

It became clear to us through our work on our self-management intervention that OSA patients wanted access to their CPAP data (adherence and efficacy) and guidance on how to improve their management of CPAP. Our initial pilot work revealed that we needed to incorporate as a central feature a review of the patient’s recent CPAP adherence and efficacy data. Efficacy data included (1) the number of residual apneas and hypopneas per hour of sleep and (2) the amount of air that was escaping between the CPAP mask and facial skin. Reviewing that data allowed patients to better understand how CPAP was helping to manage their sleep apnea, and what changes or modifications to the care management plan were necessary. Along with a large body of literature that suggests that self-monitoring and self-tracking are a central strategy for the promotion of behavioral change (and we view treatment adherence as a health behavior), our work on the development of a self-management intervention for OSA patients prescribed CPAP clearly demonstrated this as well. For that reason, we teamed up with a Web site design team at the University of California, San Diego, to design a sleep apnea/CPAP Web site around this central feature. One key component of the Web site is the section called “My Charts,” which allows patients to view their adherence and efficacy data in a variety of ways that allow for clear understanding and interpretation of how they are progressing on CPAP. Other components of the site are “My Learning Center,” “My Assessments,” “Troubleshooting Guide,” “Message Board, and “Sleep Apnea Resources.” Feedback to date indicates that not every patient will use every aspect of the site, which was not

unexpected. However, there were no aspects of the site that were rated as not useful by CPAP patients. Consistent with a patient-centered approach, we view the site as a tool that the patients can use in their own preferred way. In addition, CPAP therapists continue to have access to the patient's CPAP data and can proactively intervene as well.

The main goals of such an intervention are to attempt to increase the percentage of new CPAP users who initially try CPAP (almost a third of new users do not want to even try CPAP) and to increase the nightly adherence mean in those patients who do continue to use CPAP. We also anticipate higher levels of self-efficacy in the Web-site-plus-therapist group.

Insomnia

Insomnia is defined as an inability to initiate or maintain sleep that results in daytime consequences. Studies have found insomnia to be the most common sleep disturbance in older adults, with up to 40%–50% of those over the age of 60 reporting difficulty sleeping (Foley, Monjan, Brown, Simonsick, Wallace, & Blazer, 1995), and an annual incidence rate of 5% in those over the age of 65 (Foley, Monjan, Simonsick, Wallace, & Blazer, 1999). Insomnia complaints include difficulty falling asleep, difficulty staying asleep, early morning awakenings, chronically nonrestorative sleep, and/or poor quality of sleep. Women tend to have higher rates of insomnia than men.

Insomnia Diagnosis

The most important step in diagnosing insomnia is careful evaluation of the sleep history, including sleep habits, drug/alcohol consumption, medical and psychiatric history, and family history. Sleep testing is rarely indicated for diagnosing insomnia but may be useful when SRBD or other sleep disorders are suspected, if insomnia has been present for more than 6 months, or if it has not responded to behavioral or pharmacologic therapies. However, sleep diaries do play a very important role in obtaining relative accurate data about daily sleep patterns, associated problems or factors, and subjective sleep quality. Diaries are typically kept for 1–2 weeks, with the longer duration being better for patients who have irregular sleep habits. There is no standard format for a sleep log, but many examples have been published (Buysse, Ancoli-Israel, Edinger, Lichstein, & Morin, 2006; Monk et al., 1994).

Sleep diaries allow the mean sleep latency (i.e., the amount of time from getting into bed until the onset of

sleep) and mean total sleep time to be calculated and then compared to the patient's own subjective estimates (obtained during the sleep history). Oftentimes, there are discrepancies in the patient's perception of sleep latency or sleep time, and this information can be important. In addition, comparing a post-treatment sleep diary to a pre-treatment sleep diary is a less subjective indicator of treatment response than the sleep history because it is less likely to be affected by recall bias.

Actigraphy may be helpful when objective activity monitoring is desired. Actigraphy uses a piezoelectric accelerometer worn on the wrist to measure gross motor activity. Algorithms have been developed to distinguish rest from activity, and actigraphy has been shown to correlate very highly with sleep (Kushida, Chang, Gadkary, Guilleminault, Carrillo, & Dement, 2001). Wrist actigraphy has the key advantage of being worn across multiple days (up to one week) and can provide important data over time. Because of its more objective measurement, low patient burden, and relative ease of scoring, actigraphy can provide one important way to assess sleep-wake cycles and can be used to measure treatment outcomes for insomnia patients.

Integration of eHealth Management in Insomnia Treatment

Treatments for insomnia are comprised of behavioral, pharmacological, and combined treatment approaches. Nonpharmacological interventions are effective in the treatment of insomnia (Morin, Bootzin, Buysse, Edinger, Espie, & Lichstein, 2006; "NIH State-of-the-Science Conference," 2005) and include good sleep hygiene, behavioral therapies (stimulus control therapy and sleep restriction therapy), and cognitive-behavioral therapy. A brief summary of each intervention and how eHealth management can be incorporated follows.

Nonpharmacological Interventions

Sleep hygiene. Good sleep hygiene, or the practice of appropriate sleep behaviors, provides the basis for the behavioral approach to insomnia (see Table 28.4). Poor sleep hygiene practices can be associated with behavioral patterns that contribute to sleep disturbances. Patients should be educated on how to identify specific factors that affect their sleep. The use of alcohol, which is widely used as a sleep aid due to its ability to shorten sleep latency, should be discouraged, as it has been shown to contribute to sleep fragmentation and early morning awakenings.

28.4 | Sleep Hygiene Rules for Insomnia

Check effect of medication on sleep and wakefulness.

Keep a regular bedtime-waketime schedule.

Avoid naps or limit naps to 1 nap a day, no longer than 30 minutes.

Restrict naps to late morning or early afternoon.

Avoid caffeine, alcohol, and tobacco after lunch.

Increase overall daytime light exposure (e.g., spend more time outside, especially late in the day).

Exercise regularly.

Eat a light snack (e.g., milk, bread) before bed.

Limit liquids in the evening.

Do not spend too much time in bed.

Get out of bed if unable to fall asleep.

The main factor limiting the provision of good sleep hygiene education is that it is not taught as a skill to be developed over time. In other words, simply verbally instructing the patient to engage in a health behavior is not the same as collaboratively developing a plan and helping the patient implement that plan. Doing so via an eHealth management system helps to make this possible across larger numbers of patients. An interactive Web site where patient and provider can decide on the top two or three sleep hygiene habits that need to be addressed can be set up. A behavioral program can be started and tracked online by both the patient and provider. This need not be a long in duration, but rather 1–3 weeks, depending on the behavior and the decision made by patient and provider. The clear advantage is that not only is communication between patient and provider enabled, but the online tracking can be stored and the patient can return to it at a later date. One of the key lessons learned from the behavior change literature is that patients may need to cycle back to a behavior numerous times before it is maintained over the longer term. In other words, just as a skill is learned over time,

new health habits are formed over time as well. It may be that it takes several attempts before the new habit is learned and maintained. Using an eHealth system that allows patients to review their past attempts, learn from them, and try them again might be very effective. This eHealth system also allows for the collection of very rich data for the provider, especially when the average clinical interaction is often based on all the known limitations of patient recall. The chronic care model of a productive interaction between an informed and activated insomnia patient and a prepared and proactive care team can be powerful.

Behavioral therapies. Two commonly prescribed behavioral therapies are stimulus control therapy and sleep restriction therapy. Stimulus control is based on the belief that insomnia may be the result of maladaptive classical conditioning (Bootzin & Nicassio, 1978). Patients are instructed to eliminate all in-bed activities other than sleep, such as reading and television watching. If they are not able to fall asleep within 20 minutes, they are instructed to get out of bed until they feel sufficiently sleepy, when they can return to bed and attempt to

again fall asleep. If they are not able to fall asleep within 20 minutes, the pattern of getting out of bed until they become sleepy repeats itself. This therapy tries to break the association between the bed and wakefulness.

Sleep restriction therapy limits the time spent in bed to about 15 minutes beyond the duration of time spent asleep at night (Spielman, Saskin, & Thorpy, 1987). As sleep efficiency (i.e., the amount of sleep relative to the amount of time in bed) improves, the time in bed gradually increases.

Just as an eHealth system can be useful for helping patients change established habits related to sleep hygiene behaviors, stimulus control and sleep restriction therapy are also very amenable to an interactive Web site that is provider monitored. Simple daily checklists of stimulus control can be administered each day to ensure that the patient is following the stimulus control instructions, and if not, an interactive troubleshooting component can be added to help patients overcome commonly experienced barriers. We have found that when common problems can be “automated” online, this freed up provider time for the management of more complex issues and has the added benefit of helping the patient become a more informed and active participant—exactly what the chronic care model suggests is important for managing chronic conditions on a daily basis. We have also found that it is important to strike a balance between allowing the patient to seek out his or her own solutions via the Web site and encouraging a clinical interaction, either by communicating via the Web site, phone calls, or face-to-face visits. We have taken a stepped approach, starting with the minimal interaction necessary, and increasing the amount and nature of clinical contact as needed, and found this to work well. The key is to provide the interaction that works for the patient and is successful.

Cognitive-behavioral therapy. Cognitive-behavioral therapy (CBT) for insomnia involves educational, behavioral, and cognitive components. The educational component involves encouraging the patient to determine which factors might be predisposing, precipitating, or perpetuating the insomnia. The therapist explains that CBT is effective in that it eliminates the perpetuating factors with behavioral and cognitive strategies. The behavioral component involves the behavioral techniques (i.e., stimulus control, sleep restriction therapy) described above. The cognitive component deals with the maladaptive thoughts or dysfunctional beliefs that the patient has about the insomnia.

CBT has been shown to be as effective as medications in the short run and to have better long-term outcomes in the treatment of insomnia, in both younger and older

adults (Morin, Colecchi, Stone, Sood, & Brink, 1999). In an 8-week double-blind longitudinal outcome study, CBT, an intermediate-acting benzodiazepine (temazepam), a combined CBT/temazepam condition, and a placebo condition were compared in a sample of older adults (Morin, Bastien, Brink, & Brown, 2003). Compared to baseline, all three active treatments reduced night wakings at post-treatment; however, only CBT alone and CBT/temazepam were associated with continued improvement at 3-, 12-, and 24-month follow-up interviews. In addition, one study found that even two 25-minute CBT sessions for insomnia are effective in reducing nocturnal awakenings, which may be a more practical approach in the primary care setting. The NIH 2005 State-of-the-Science Conference on insomnia concluded that CBT has demonstrated efficacy, that CBT is as effective as prescription medications for brief treatment of chronic insomnia, that the beneficial effects of CBT (in contrast to those produced by medications) may last well beyond the termination of treatment, and that there is no evidence that CBT produces adverse effects, all of which make CBT the most effective treatment for insomnia. Although pharmacologic treatments may be of more immediate help in the acute treatment phase, nonpharmacological or combined approaches may be more effective for long-term clinical gains.

CBT takes a good deal of planning to incorporate effectively into an interactive Web site. Because CBT is a multifaceted psychological intervention, it is important that any use of an eHealth system for this purpose take into full consideration the need for careful provider oversight of treatment progress. That having been said, Tate and Zabinski (2004) suggested that one of the most powerful uses of eHealth systems may be as adjunctive treatment components to face-to-face therapeutic sessions, such as CBT. They discuss several ways eHealth systems can be a useful adjunct to therapies such as CBT: (1) a personal digital assistant or similar device can be used to assess important constructs, such as daytime sleepiness or fatigue, in real time throughout the day; (2) an eHealth system can be used to deliver a portion of the treatment, which has the effect of reducing the total number of therapist contact hours; and (3) an eHealth system can be used to deliver an intervention component that standard therapy may not be able to, such as virtual reality therapy, or for the selection or creation of a personalized relaxation program. Regarding use of a PDA or a cell phone to assess constructs in real time, readers should note that an entire field called ecological momentary assessment has developed over the last decade (Shiffman, Stone, & Hufford, 2008).

Many of these components have not been fully evaluated within the context of insomnia, and this now represents an emerging area of much needed research. Interestingly, several insurers are paying for online treatment of insomnia despite the current lack of evidence regarding the efficacy or effectiveness of online insomnia therapy (Kritz, 2008). Given that insurers typically demand proof of treatment efficacy, this might be taken as an encouraging sign.

Pharmacological Interventions

Historically, a number of different classes of medications have been used to treat insomnia in the elderly, including sedative-hypnotics, antihistamines, antidepressants, antipsychotics, and anticonvulsants. The 2005 NIH State-of-the-Science Conference on Insomnia concluded with several recommendations regarding the use of medications for insomnia. All antidepressants have potentially significant adverse effects, raising concerns about their risk-benefit ratio. Barbiturates and antipsychotic medications have significant risks, and thus their use in the treatment of chronic insomnia was not recommended.

There is particular concern about the use of antihistamines for insomnia in the elderly, even though these drugs are easy to obtain and are inexpensive. In a study of 426 older hospitalized medical patients, all >70 years, nearly one-third were given 25–50 mg diphenhydramine. Compared to patients who were not given diphenhydramine, these patients were shown to be at increased risk for any delirium symptoms, inattention, disorganized speech, altered consciousness, urinary catheter placement, and longer median length of stay. A dose-response relationship was demonstrated for most adverse outcomes (Agostini, Leo-Summers, & Inouye, 2001). The NIH concluded that there is no systematic evidence for the efficacy of antihistamines, yet there are significant concerns about the widespread use of and risks with these agents, particularly in older patients.

Sedative-hypnotic medications are at times appropriate for the management of insomnia, and choosing the sedative-hypnotic that best fits the specific complaint related to insomnia is the key to using this class of medications successfully. Potentially harmful effects must be taken into account when sedative-hypnotics, particularly benzodiazepines, are prescribed to the elderly. The administration of long-acting hypnotics can cause adverse effects such as excessive daytime sleepiness and poor motor coordination, which can lead to injuries. In the elderly, the risk of falls, cognitive impairment, and respiratory depression are of particular

concern, although some recent studies have suggested that while insomnia is a risk for falls, use of hypnotics is not (Avidan, Fries, James, Szafara, Wright, & Chervin, 2005). Chronic use of long-acting benzodiazepines can lead to tolerance and withdrawal symptoms if abruptly discontinued, and the benefits of these agents for long-term use have not been studied with randomized clinical trials. Additionally, use of these medications has the potential to exacerbate coexisting medical conditions such as hepatic and renal disorders.

The newer selective short-acting type 1 GABA benzodiazepines receptor agonists (i.e., zolpidem, zaleplon, eszopiclone) have been shown to be effective in older adults, with a low propensity for causing withdrawal, dependence, tolerance, or clinical residual effects. All were shown to decrease the time it takes to fall asleep and/or by increase total sleep time. In younger adults, eszopiclone has been found to be safe and effective in the long-term treatment of chronic insomnia. However, long-term studies have not yet been conducted in older adults. Ramelteon, a melatonin agonist, has also been shown to be safe and effective in the treatment of insomnia in older adults. The NIH has concluded that while the older benzodiazepines are safe in the short-term treatment of insomnia, the frequency and severity of adverse effects are much lower in the newer non-benzodiazepines (“NIH State-of-the-Science Conference,” 2005). However, the NIH panel expressed significant concerns about the risks associated with the use of these medications by older adults.

Given the potential concerns regarding the use of medications for insomnia patients, there are a number of ways that eHealth methods can be applied to pharmacological interventions. One involves providing improved patient education about the benefits and the risks, especially long-term potential for abuse and side effects. An eHealth approach can be used to provide a multimedia presentation tailored to the patient. Another concerns the role of medication adherence. One study examined the use of a medication box that was interlinked via telematics with an electronic health record (Schmidt, Sheikzadeh, Beil, Patten, & Stettin, 2008). The key advantage of such an eHealth system is the real-time upload of the opening of the medication box, and the availability of that data to care providers. The study found that compliance and mental health were significantly improved in the experimental group relative to the control group. Interestingly, while the medication box was well accepted, just under half of the participants said that they would continue to use the medication box. The participants believed that they did not need “behavioral” monitoring on an ongoing basis

(i.e., they only needed it on an interim basis) and that it was too “invasive” to use regularly. This raises questions about when and how such an intervention might be used in the future. Clearly, as was discussed above, one approach might be to use such interventions in a stepped care approach, where the interventions are used on an as-needed basis depending on clinical need.

It is important to note that a number of meta-analyses have shown that both behavioral and pharmacological approaches have effects on insomnia (Morin, Culbert, & Schwartz, 1994; Smith et al., 2002). It is thought that the evolving evidence base supports a combined pharmacologic and behavioral approach, each potentiating the other (Mendelson, 2007). In other words, the more the medication physiologically helps the patient sleep better, the greater the effect of the behavioral approach is, and vice versa. As was discussed above, the use of an eHealth system designed to facilitate a combined approach for the insomnia patient can be powerful. The key features of such a system would include daily support of treatment implementation, tracking of intervention “dose,” and close monitoring of key outcomes, all of which could be available to both patient and provider to enable patient-centered collaborative care.

Narcolepsy

While narcolepsy is not nearly as prevalent as SRBD, it does represent the second most common cause of disabling daytime sleepiness after SRBD (Zeman et al., 2004). Narcolepsy with cataplexy is estimated to have a prevalence of 25–50 per 100,000 people, and an incidence of 0.74 per 100,000 person-years (Longstreth, Koepsell, Ton, Hendrickson, & van Belle, 2007). It is equally common in men and women (Ohayon, Priest, Zulley, Smirne, & Paiva, 2002; Silber, Krahn, Olson, & Pankratz, 2002). Narcolepsy typically begins in the teens and early 20s but can occur as early as 5 years of age or after 40 years of age. Narcoleptic symptoms worsen during the first few years and then persist for life (Okun, Lin, Pelin, Hong, & Mignot, 2002). Narcolepsy is thus classified as a chronic sleep disorder.

Narcolepsy can be viewed as a disorder of the control of the sleep-wake state in which elements of sleep intrude into wakefulness, and elements of wakefulness intrude into sleep. The overall effect is daytime sleepiness with varying amounts of other key features, including cataplexy, hypnagogic hallucinations, and sleep paralysis. About one in three patients have all four of these key symptoms, and therefore the diagnosis of narcolepsy is considered even in patients with sleepiness alone.

Narcolepsy Diagnosis

A diagnosis of narcolepsy is based on a thorough history, physical exam, and neurologic exam, with a focus on looking for features that support the diagnosis and exclude other causes of sleepiness (e.g., insufficient sleep, OSA). In addition, diagnostic testing, including an overnight polysomnography (PSG) followed by a Multiple Sleep Latency Test (Littner et al., 2001), should be performed. The Multiple Sleep Latency Test is a napping study that is used to see how quickly someone can fall asleep in quiet situations during the day and is the gold standard for measuring the amount of daytime sleepiness. During the test, the patient is given four or five opportunities to nap every 2 hours. On average, healthy patients fall asleep in about 10–15 minutes while people with narcolepsy often fall asleep in less than 5 minutes, providing what is considered objective evidence of their level of daytime sleepiness. In addition, the nap studies can be scored for what are termed sleep-onset REM periods. If found in two or more naps, this is highly suggestive of narcolepsy.

Integration of eHealth Management in Narcolepsy Treatment

The two main treatment modalities for the management of narcolepsy are nonpharmacologic and pharmacologic therapy interventions. There are several nonpharmacological interventions that may benefit the patient with narcolepsy, including (1) avoiding certain drugs; (2) napping/sleep hygiene; and (3) psychosocial support. A well-designed eHealth system can help with each one of these nonpharmacological interventions.

Avoiding certain drugs. There are certain prescribed, over-the-counter, and illicit drugs that can produce daytime sleepiness or insomnia. Such drugs should be avoided by patients with narcolepsy. An eHealth system can provide lists of these medications to both patients and providers to help with the identification of problematic drugs. For example, an eHealth system can be created that allows a patient to enter his or her current medications to find out which might be contributing to daytime sleepiness or insomnia. Patients could then work collaboratively with their sleep provider or their primary care physician to decide on alternative options.

Napping/sleep hygiene. Behavioral interventions are often very helpful for gaining maximal control of narcoleptic symptoms. We have already discussed the how good sleep hygiene behaviors can be implemented with an eHealth system. What is specific to narcolep-

tic patients, however, are the scheduled naps (Bassetti, 1999). One or two approximately 20-minute well-timed naps will often improve sleepiness for 1–3 hours. Some patients only benefit from long naps (Mullington & Broughton, 1993). Sleep deprivation may worsen narcolepsy symptoms and therefore patients should be counseled to maintain a regular and adequate sleep schedule (Rogers, Aldrich, & Lin, 2001), and this can be tracked by the patient, who can work collaboratively with his or her provider to ensure an acceptable sleep schedule is being kept. An online diary can be maintained and key symptoms tracked to show the narcoleptic patient the potential benefit of these planned naps. With time, such tracking can reveal the ideal napping schedule for the narcoleptic patient.

Psychosocial support. Narcolepsy is chronic and debilitating, often causing psychosocial and work-related problems for patients, which then often lead to problems with economic and social responsibilities. Because individuals with narcolepsy often live with the condition for a decade before being diagnosed, patients have the additional burden of coping with misperceptions about the causes and the involuntary nature of their symptoms. Common misconceptions, even among medical caregivers, are that sleep attacks and cataplexy (emotionally triggered muscle paralysis resulting in partial or complete collapse) are manifestations of poor motivation, denial, or avoidance. Thus, patients often benefit from participation in support groups that focus on coping skills and identification of community resources to assist with administrative and medical issues.

Many patients benefit from these nonpharmacologic approaches, but most also require medications that reduce sleepiness and cataplexy. An eHealth system that is comprised of a multimedia presentation of common misconceptions could help educate patients. Online support groups and access to sleep providers can provide the necessary psychosocial support that the patient requires.

CURRENT ISSUES IN CLINICAL SLEEP PRACTICE

Role of Centers for Medicare & Medicaid Services Decisions on Practice

This chapter would not be complete without mention of the impact of recent decisions of the Centers for Medicare & Medicaid Services on the practice of medicine,

and on how these decisions encourage or discourage new practice models.

In March of 2008, the Centers for Medicare & Medicaid Services published the “Decision Memo for Continuous Positive Airway Pressure (CPAP) Therapy for Obstructive Sleep Apnea (OSA),” which addresses the role of home sleep testing in diagnosing sleep apnea. Previously, sleep apnea was primarily diagnosed through an overnight sleep test in a dedicated sleep clinic. This memo allows for reimbursement for portable sleep testing or HST in the patient’s home environment. Given that the cost of HST is significantly less than that of overnight testing in the sleep clinic, there is now the potential for cost savings to the health care system for the use of HST for diagnosing SRBD. The main decision for the SRBD field will be whether those cost savings are credited back to the system, or if they will be redeployed, or realized on the clinical management side. Clearly, our preference is for the latter, given that optimal chronic care model requires patient-centered collaborative care. The main question would then concern whether the costs saved by HST would be negated by the extra cost of optimal chronic care or not. If there are extra costs associated with optimal chronic care, the next question would be whether those costs are worth the potential reduction in mortality and morbidity associated with SRBD. That is an empirical question that would need to be addressed by a well-designed study.

While it is commonly thought that the application of an eHealth system would result in reduced costs, oftentimes this is not the case. There are costs associated with the development and maintenance of an eHealth system, as well as hardware and software costs. In addition, there is the potential for increased patient contact, at least initially, relative to standard or usual care. Future studies will need to look at the cost-effectiveness of eHealth systems specific for chronic sleep disorders.

Technological advancement is perhaps the major factor enabling the move toward the use of HST. Such advances have made sophisticated monitoring in the home quite feasible for a subset of patients. Even when sleep staging with electroencephalography, electrooculography, and electromyography is not obtained, a plethora of other information is now available with some type III studies. There are four main types of sleep study devices as defined by the Center for Medicare and Medicaid Services. Type III devices are typically used in the home sleep environment and are characterized by being portable; unattended (i.e., the sleep technician is not present); typically do not record the signals required to measure sleep stage;

and typically include the following channels (two respiratory movement or airflow channels, one electrocardiogram or heart rate channel, and one oxygen saturation channel). With some of the more sophisticated type III devices, secure digital card recording and wireless transmission can totally eliminate the usual tethering and resultant sleep disruption. Portable monitoring can even include remote attendance with real-time viewing of all recorded channels and live videography as well. Communication to the patient by phone can facilitate correction of any displaced sensors. As evidenced in the following case studies, portable monitoring, when properly administered and carefully interpreted, can serve as an accurate testing modality in the resolution of sleep disorders.

Prudent application of home testing can potentially bring the undiagnosed population with sleep problems under mainstream medical care. Rather than being the end of quality sleep care as we know it, it can actually enhance it. It can be used to identify those who not only suffer from the symptoms of sleep disorders but are at risk for resultant poor health outcomes and are therefore major consumers of health care resources. HST can be used to validate the adequacy or inadequacy of therapy in both the short and long term. It can be used to provide continuity of care as an objective tool of benefit or lack of it. With judicious application, these goals can be accomplished and an enormous amount of health care dollars can be saved. This is a win-win situation that will allow us to provide more care to more patients for less cost, yet at a high level of quality.

Technology and innovation have made all of this possible. However, HST puts a much greater onus on the human ingredient in this equation. Clinical evaluation must be stringent enough to identify who is and who is not a candidate for home study. Careful scrutiny of data, which on the surface may seem to be quite simple, by skilled interpreters will be required to identify which studies are either inadequate or inaccurate. Strength of conviction will be necessary to push forward the more expensive and seemingly redundant in-lab studies among those who need them, despite patient or payer resistance. Perseverance in providing long-term continuity of care and follow-up, both clinically and objectively, using HST, will be essential to sustain benefit. Payers must be willing to pay the tariff for the necessary level of study and repeat studies when required.

While HST is not for everyone, it is a valuable tool that needs to be individually tailored to a given patient at a particular time in the course of the patient's evaluation, treatment, and follow-up. Greater skill, discretion, and clinical judgment will be required by technologists

and sleep specialists alike in order to allow this technology to meet its potential.

CONCLUSION: AN eHEALTH APPROACH TO CHRONIC SLEEP DISORDERS

The purpose of this chapter was to describe and provide support for a model that combines state-of-the-art health information technologies with patient-centered collaborative care for the treatment of chronic sleep disorders. We used the chronic care model as an overarching framework that describes the essential elements of chronic care that allow for ongoing productive interactions between an informed, activated patient and a prepared, proactive provider team. The chapter systematically reviewed two broad topics—eHealth and patient-centered collaborative care—and then described how they might be combined and applied to specific sleep disorders. This approach's potential to improve the clinical management of chronic sleep disorders is exciting, and an area of promising future research efforts.

Neurofeedback: Research-Based Treatment for ADHD

Kirk D. Little
Joel F. Lubar
Rex Cannon

Neurofeedback is a powerful tool that can be used to enhance attention, mood, and higher-order cognitive abilities, including IQ. Advances in brain-imaging technology have vastly increased our understanding of the brain and its functioning. We now know that human beings possess the ability to alter or regulate their own brain activity and that this can be done without invasive medical procedures or chemicals. Neurofeedback involves leveraging the brain's power to change or even correct itself, thereby potentially decreasing suffering and improving one's quality of life.

In this chapter, we will discuss neurofeedback and its use in the treatment of attention-deficit/hyperactivity disorder. Because neurofeedback can best be understood as simply one form of learning, we will first begin by providing a brief refresher of learning theory. We will discuss the conceptualization of the mechanisms involved in learning to change or regulate EEG activity when one is provided proper feedback. We will demonstrate how neurofeedback induces performance and behavior changes via a neuroplastic process of brain modification and growth. We will summarize the most recent empirical research on neurofeedback, which provides a substantial research base demonstrating its effectiveness, the limited side effects when done sys-

tematically, and the enduring effects and benefits. Next we will discuss the process of neurofeedback. What does neurofeedback look like and what exactly does a practitioner do when providing neurofeedback to a patient?

We will then review the neurophysiology of ADHD, outlining typical brain mechanisms involved, as well as the electroencephalogram (EEG). We will discuss the prevalence and components in the subtypes of ADHD, including the inattentive, hyperactive-impulsive, and combined types. We will review the research that supports neurofeedback as an effective form of treatment for patients with ADHD. We will then review LORETA neurofeedback and a recent research study using LORETA neurofeedback with two patients with ADHD.

Lastly, we will provide resources and additional information on appropriate training and certification in neurofeedback.

NEUROFEEDBACK: THEORY AND DEVELOPMENT

Neurofeedback is a process in which a patient receives feedback about his or her own brain functioning and,

over time, learns to develop control over that functioning. Neurofeedback is effective due to the brain's neuroplasticity. Neuroplasticity is defined as the reorganization of and changes in connections between linked neurons in the brain (Nasrallah & Tolbert, 1997; Pallagrosi, 1993; Shaw, Lanius, & van den Doel, 1994; Swann, Pierson, Smith, & Lee, 1999). It is a process that is initiated by a challenge, and we now know that, with repeated challenges, brains change and grow (develop and reorganize synapses; Machado et al., 2008; Self & Choi, 2004; Shashoua, 1985; Sunderland & Tuke, 2005). This appears to be the case for all forms of new learning.

Receiving feedback regarding our performance through our senses gives us the ability to modify our behaviors. Although this has not yet been tested directly, we can infer that neurofeedback accelerates neuroplasticity by influencing the strengthening of neural networks (Cannon, Congedo, Lubar, & Hutchens, 2009) because of the near-instantaneous nature of the feedback loop and the extremely high number of trials that can be completed in a very short period of time (e.g., 900 in a half-hour feedback session). This equates to 18,000 successful trials in only 10 hours of training.

The now famous London taxi driver study conducted at University College London and published in the *Proceedings of the National Academy of Sciences* is worth outlining in some detail in order to provide a useful example of what is meant by neuroplasticity. Researchers Maguire and colleagues (Maguire, Frackowiak, & Frith, 1997; Maguire, Woollett, & Spiers, 2006) used structural magnetic resonance imaging (MRI) to compare the brains of London taxi cab drivers with non-taxi drivers.

London taxi drivers must apprentice for 2 years before being licensed, a period colloquially termed "being on the knowledge." Drivers learn to find the most arcane locations and can describe the history and scenery on the way there. The drivers' visual-spatial memory and navigational skills are constantly challenged in order to accommodate their passengers' requests.

Brain scans of the taxi drivers pre- and post-apprenticeship and over longer terms of duty revealed that part of their hippocampi nearly doubled in size compared to others who had not undergone training (Maguire et al., 1997, 2006). The extraordinary challenge faced by the taxi drivers during their apprenticeships is proposed to have initiated the increased development of posterior sections of their hippocampi, with greater growth in proportion to the time spent on the job, or "on the knowledge." The brain's ability to grow and change in response to new learning defines neuroplasticity.

Operant Conditioning

To facilitate growth and change in the brain, we must fully understand the process of how we learn. After 100 years of research, a great deal of evidence has accumulated on how to best facilitate learning in organisms. Edward Thorndike, the pioneer in conditioning research, studied the learning of cats by putting them in puzzle boxes. The cats had to learn how to escape by figuring out which device to pull. As the trials proceeded, the cats were able to escape more quickly, indicating that they had learned. Thorndike observed that this learning was gradual and orderly. He concluded that the cats didn't use reason but instead learned through trial and error, or what he called the "Law of Effect." Responses that resulted in satisfaction gradually turned into habits. Responses that resulted in annoyance were eliminated.

Thorndike also described the "Law of Exercise," according to which the stimulus-response connections that are repeated are strengthened, and those stimulus-response connections not used are weakened. This is what we call today the "use it or lose it" dictum. This is a connectionist theory that we describe in terms of new dendritic branches and stronger neuronal connections. Thorndike believed that through experience, neural connections are formed between perceived stimuli and emitted responses.

B. F. Skinner and others helped us to learn the reinforcement schedules that are optimal for learning and for resisting extinction. These are the principles that guide the neurofeedback clinician on a daily basis in the clinic. The behavior being trained is the EEG, the operator is the patient, and the reinforcement is visual and auditory stimuli that indicate success at the task. The felt experience of focused attention or motoric calm is paired with the visual and auditory display, so the subject gets near-immediate feedback (<250 msec) about the state of his or her brain and attention. Neurofeedback is defined simply as operant conditioning of the EEG.

EEG Primer

EEG stands for electro-encephalo-graphy

Electro = electricity

Encephalo = brain

Graphy = written down or represented

In other words, EEG is a measure of the electricity in one's head.

An EEG is what we see when we record the electrical activity generated by cortical neurons in the brain on the scalp as it is amplified and converted through digital signal processing into a line graph. EEG is also referred to colloquially as “brain waves” because of how the measurements are most commonly displayed.

As one can see from Figure 29.1, rather than displaying random activity, EEG recordings tend to have a rhythmic quality. Looking at brain waves often enough will lead one to recognize consistent patterns. Botanists can easily tell the difference among trees. Electro-physiologists can easily tell the difference among brain waves. These regular occurrences in the EEG can be readily categorized and quantified, and then correlated with cognition, affect, and behavior.

often a wave occurs, is measured in cycles per second, or hertz, and morphology, or shape, is described categorically.

- (1) Amplitude = size (big or small), micro-volts
- (2) Frequency = speed (fast or slow), cycles per second (hertz)
- (3) Morphology = shape (sharp, spike, square, wicket shaped, spindling, synchronous, dyssynchronous, etc.)

The frequency waves are categorized by the following:

0–4 Hz	4–8 Hz	8–12 Hz	13–36 Hz	36–42 Hz
Delta	Theta	Alpha	Beta	Gamma

Physical Properties of the EEG

The three most common ways of categorizing EEG are by size, speed, and shape, or the three S's. Amplitude, or size, is measured in micro-volts; Frequency, or how

Clinical Correlates of the EEG

There is a close association between the speed of EEG frequencies and the arousal state.

Figure 29.1 EEG sample from LNFB in twins.

- (1) Slow brain waves in the delta range (approximately 0–4 Hz) are primarily found during deep sleep.
- (2) Slightly faster theta waves (approximately 4–8 Hz) are often associated with drowsiness and early sleep stages
- (3) The alpha frequency (approximately 8–12 Hz) is characteristic of a relaxed, waking state.
- (4) Faster frequencies in the beta (approximately 12–30 Hz) and gamma ranges (<30 Hz) are associated with more aroused active cortical processing during mental operations in the alert brain.

THE PROCESS OF NEUROFEEDBACK

Through the use of sensors to detect the brain's electrical output through the scalp, a representation of that output can be displayed digitally on the computer nearly instantaneously. This can be displayed to the patient in the form of the actual wave itself, or in the form of a computer game. When this information is fed back to the person he or she can become aware of his or her own brain state/functioning. When people are aware of ongoing activity of their brains in real time through the feedback process, they can learn to modify those processes and learn to exert willful control over their EEG. This process is defined as neurofeedback.

A person is then “rewarded” when his or her EEG is in the desired state. This reward may take various forms. It can be auditory in the form of a pleasant bell or song, or visual in the form of a fish jumping over a pond, or it can be a combination of both auditory and visual cues.

The number of reinforcements are usually set between 8 and 20 per minute, with some smaller children responding best to up to 30 reinforcements per minute. That amounts to up to 900 trials in a 30-minute session. This makes for a relatively rapid learning curve, whereby significant changes can be made in the EEG in a relatively short period of time, and these changes can lead to fairly dramatic changes in behaviors.

NEUROFEEDBACK IN SUMMARY

There are many tools a clinician can use to help patients reach their goals, and one of the most powerful tools we use is neurofeedback. We propose that to appreciate the power of this approach, all one needs is a basic understanding of the principles of learning theory and the knowledge that with all learning comes brain changes

as a result of what we call neuroplasticity. The two are really one and the same. Thanks to modern neuroimaging techniques, we can see the changes in the brain that accompany changes in learned behaviors.

We define neurofeedback as operant conditioning of the brain's electrical activity. Another way of saying the same thing is that neurofeedback is a form of rapid associative learning that accelerates the neuroplastic process. As this process occurs, so do subsequent changes in behaviors (action, feelings/moods, thoughts, levels of baseline arousal/reactivity). Additionally, this process can stimulate both positive and negative changes (e.g., make people more agitated or more easily distracted/forgetful, worsen seizures) or better (e.g., make people more focused/attentive, calmer, or more adaptable, or have a better memory).

Researchers have shown neurofeedback to have beneficial impact on a variety of mental health and medical conditions including epilepsy, learning and developmental disabilities, anxiety disorders, PTSD, sleep disorders, depression, addictive disorders, brain injury, stroke, fibromyalgia, headache, and cognitive decline with aging. It can also result in academic-cognitive enhancement. (Hammond, 2006, 2007).

Neurofeedback has also been shown to be an effective form of treatment for patients with ADHD. In the following section, we will discuss the neuroanatomy of ADHD. We will also provide an overview of the research that has successfully used neurofeedback with this patient population.

NEUROANATOMY/PHYSIOLOGY OF ADHD

Abnormal in Size

We now have sufficient evidence to make the claim that ADHD brains are different in volume and functional connectivity from non-ADHD brains. We know this mostly from MRI studies that have demonstrated that ADHD brains are smaller in certain areas (Berquin et al., 1998; Durston et al., 2004; Mostofsky, Mazzocco, Aakalu, Warsofsky, Denckla, & Reiss, 1998; Semrud-Clikeman, Steingard, Filipek, Biederman, Bekken, & Renshaw, 2000). The brain areas involved in the control of movement, such as the basal ganglia, and in the control of executive functions, such as the deep white matter in the frontal lobes, the corpus callosum, and the anterior cingulate cortex, all show smaller volume. Thus, MRI evidence points to a frontal-striatal

substrate of ADHD. However, our understanding of structural problems has not progressed much since the mid-1990s, when many of the initial MRI reports became available.

Decreased Glucose Metabolism and Hypoperfusion

Do larger cerebral volumes equate to smaller degrees of impairment? Or, put another way, do bigger brains equal better functioning? At his Cingulate Cortex Research Laboratory at Harvard, Bush (1999) addressed this question in a study using functional neuroimaging of the cingulate cortex in people with ADHD.

Cingulate means “girdle” or “belt,” and it surrounds the corpus collosum. The anterior or front part of it is called the anterior cingulate cortex, or ACC. The top, or dorsal part, of the ACC is the cognitive division of the ACC (ACCcd). This part of the brain may be important for:

- (1) Modulating attention and executive functions
- (2) Monitoring competition and conflict
- (3) Novelty and error detection
- (4) Working memory (Bush, Luu, & Posner, 2000)

To determine functional impairment of the ACC, Bush gave the counting Stroop test to healthy adults. He found that the more cognitive interference there was in the task (as measured by longer reaction times), the greater the degree of ACCcd activation. In other words, in normal, non-ADHD adults, the cognitive division of the ACC was reliably “activated” during the Stroop test during set 2. He then repeated the test on adults with ADHD and found they did *not* activate the ACC. Instead, they activated a totally different area called the insular cortex.

The counting Stroop test appears to be somewhat like, as Bush put it, a cardiac stress test for the ACCcd; that is to say that the more taxing the task is on the executive system, the more the ACC exerts executive engagement (in normals, anyway). This line of research revealed ACC dysfunction specific to ADHD; more importantly the ADHD subjects seemed to compensate for impairment of their ACC (or the ACCcd-fronto-striatal network) by recruiting a different, less efficient, response pathway via the insula.

Based on this and many other studies, we have come to understand that both brain structure and brain function seem to be abnormal in ADHD.

EEG PATTERNS OF ADHD BRAINS

The association between EEG rhythms and arousal/activational state is helpful to our understanding of the relationship between predictable functional brain abnormalities and ADHD. It has been established through the use of magnetic resonance imaging (MRI) that the prefrontal lobes, caudate, cerebellar vermis, and cerebellum in ADHD brains are smaller in size than those of normal controls (Berquin et al., 1998; Durston et al., 2004; Mostofsky et al., 1998; Semrud-Clikeman et al., 2000). Other neuroimaging techniques demonstrate metabolic and blood oxygenation level-dependent (BOLD) response differences in specific regions in ADHD brains during resting baseline (Langleben et al., 2002; Lee et al., 2005; Schweitzer et al., 2003). It is no surprise, then, that when we use quantitative EEG (qEEG) to measure brain function, we also see predictable differences in the brains of those with ADHD. These EEG differences among people with ADHD have been shown in a number of studies (Chabot, Merkin, Wood, Davenport, & Serfontein, 1996; Chabot & Serfontein, 1996; Clarke, Barry, McCarthy, & Selikowitz, 2001a, 2001b; Janzen, Graap, Stephanson, Marshall, & Fitzsimmons, 1995; Mann, Lubar, Zimmerman, Miller, & Muenchen, 1992; Monastra et al., 1999). With some regularity, researchers across these groups have found subtypes in ADHD, as defined by EEG, using clustering, factor analysis, and principal component methods.

Usually when measuring brain waves, one collects data from multiple sites on the scalp. This can be done with as few as 2 sites, or over 100. Nineteen electrode sites across the scalp were used to collect current EEG databases available for analytic purposes according to a standard system called the 10/20 system (see Figure 29.1).

There are other aspects of the EEG that one can measure by comparing the EEG at two different sites. These are called phase and coherence. For an in-depth understanding of the relevance of coherence as a measure of network functional connectivity, refer to chapter 18. The qEEG phenotypes (recurring brain-wave patterns) for ADHD are:

- (1) Hypoarousal types
 - (a) High theta (the sleepy brain)
 - (b) High alpha (the idling brain)
- (2) High-beta type
 - (a) High beta (the anxious/agitated brain)
 - (b) Spindles (cognitive inefficiencies)

- (3) Maturational lag
- (4) Others (MTBI, coherence-phase abnormalities, developmental lag)

Too Much Slow Activity (Theta or Alpha or Both—Thalpha)

The most common finding in the literature is elevated slow-wave activity and decreased fast activity over frontal and central areas. A thorough outline of this history offering consistent findings of EEG abnormalities in children with behavioral disturbances, the most prevalent of these being increased slow-wave activity in frontal and central regions of the cortex, can be found elsewhere. As pointed it out in comprehensive reviews (Barry, Clarke, & Johnstone, 2003; Barry, Johnstone, & Clarke, 2003), there are many studies dating back to the 1930s, before the EEG was subject to computerized quantitative spectral analysis (Jasper, 1958a; Jasper & Radmussen, 1958), that found similar patterns of EEG increase in slow-wave activity, mainly in frontal areas in children with behavioral problems (Capute, Niedermeyer, & Richardson, 1968; Green, 1961; Kennard, 1949a, 1949b; Wikler, Dixon, & Parker, 1970).

More recent research using quantitative EEG methods, which began in the early 1970s (Satterfield, Cantwell, Lesser, & Podosin, 1972), has supported the same general findings: that children with ADHD have higher-amplitude slow activity than normal controls, slower mean maximum amplitude, a higher percentage time of delta and slow theta, lower percentage time of alpha (Matsuura, Okubo, Toru, Kojima, He, Shen, & Lee, 1993), and lower power in alpha and beta bands (Dykman, Holcomb, Oglesby, & Ackerman, 1982).

Chabot and Serfontein (1996) found increases in theta, primarily in the frontal midline. They also found higher relative alpha and a diffuse decrease in mean frequencies in alpha and beta power in some children with ADD, in addition to interhemispheric asymmetries and intrahemispheric abnormalities. Research has shown increased absolute theta and low alpha frontally and reduced relative beta in posterior regions in adolescent populations. Other studies of children, adolescents, and adults have found that high theta activity remains elevated into adulthood, and others have found increased theta at all sites with reduced relative power in alpha and beta frequencies (Bresnahan, Anderson, & Barry, 1999; Clarke, Barry, McCarthy, & Selikowitz, 1998; Lazzaro, Gordon, Whitmont, Plahn, Li, Clarke, Dosen, & Meares, 1998).

Rather than focus on just one band of activity, some researchers have pointed out that ratios may be more reliable as an indicator of ADHD (Monastra et al., 1999). The two most often cited are the theta-to-alpha ratio and the theta-to-beta ratio. Lubar (1991) showed that people with ADHD have a greater theta-to-beta ratio at all sites than controls, with the greatest difference in the frontal sites. This finding was repeated by Janzen et al. (1995). Monastra et al. (1999) found theta-to-beta ratios to be higher in ADHD patients and repeated this test with hundreds of patients. Clarke et al. (2001b) used both the theta-to-alpha and theta-to-beta ratios to differentiate normal children from those with ADHD.

Differences between ADD inattentive types and ADHD combined types have been shown to be mainly in the severity of these ratios. The same finding is apparent for girls versus boys, to the extent that boys are more likely to have more severe symptom manifestation.

Too Much Fast Activity (Beta or Beta Spindles)

In a smaller subset (somewhere between 15% and 22%), people with ADHD have elevated fast activity, mainly over frontal areas as well.

Clarke et al. (2001b) found that 15%–20% of children with ADHD combined type have excessive high-beta. Chabot and Serfontein (1996) showed 13% of the sample had high-beta, and Arns, Gunkelman, Breteker, and Spronk (2008), in a more recent sample, recorded that 22% of their ADHD sample were the high-beta type.

In one review of 150 adult patients seen at the ADD Centre in Toronto, the Thompsons (1998) found 80% had the typical slow-wave excess, and 20% had what they called “busy brains.” They found that about 40% of the adults with high theta-to-beta ratios also had high beta in excess, or spindling beta bursts. Fifty percent of their adult clinic sample had the excessive beta profile, either alone or in combination with high theta.

Because Clarke’s high-beta group responded positively to stimulants, it appears that excessive frontal beta may reflect a frontal processing problem or additional problems that are comorbid with ADHD.

Coherence Abnormalities

Our ability to categorize patients with ADHD into subtypes using EEG continues to evolve. We have come to understand that what looks like a similar behavior pattern on the outside can look very different on the inside in terms of brain functioning. Some studies have found

coherence abnormalities in children with ADHD, but the results need to be replicated before any firm conclusions can be made. For an in-depth understanding of the relevance of coherence as a measure of network functional connectivity, refer to chapter 18.

What all this points to is the fact that children who receive a diagnosis of ADHD as a result of self-reports and other reports of symptoms comprise a heterogeneous group with unique underlying abnormalities in their EEGs.

NEUROFEEDBACK FOR THE TREATMENT

Barry Sterman and Joel Lubar are considered pioneers of neurofeedback, and their early revolutionary research has made a significant contribution to our understanding of how neurofeedback works. They first successfully applied neurofeedback to various forms of epilepsy in animals and humans (Sterman, Macdonald, & Stone, 1974; Sterman & Wyrwicka, 1967; Sterman, Wyrwicka, & Howe, 1969; Sterman, Wyrwicka, & Roth, 1969). Lubar noticed that in a few cases, the epileptics showed decreased hyperactivity. He had the idea of applying neurofeedback to a child with “hyperkinesia” independent of the epilepsy issue (Lubar & Shouse, 1976, 1977).

Because it was a single case study, he used an ABA reversal design, something that is common in the autism literature. This study was the first to employ operant conditioning of the sensorimotor rhythm (SMR, 12–14 Hz) in hyperkinesia (now ADHD). SMR had previously been demonstrated to reduce seizure incidence in epilepsy (Sterman, Howe, & Macdonald, 1970).

The results of several months of EEG biofeedback training showed a substantial increase in SMR motor inhibition, as gauged by laboratory measures of muscular tone (chin EMG) and by a global behavioral assessment in the classroom. Opposite trends in motor inhibition occurred when the training procedure was reversed, and feedback presentations were contingent on the production of activity at 4–7 Hz in the absence of activity at 12–14 Hz. The behavioral manifestations of this training protocol were increases in cooperation, attention, and schoolwork behaviors, with reductions in oppositional, self-stimulation, and out-of-seat behaviors.

Of particular interest was that the undesired behaviors returned with a reversal in the training protocol and the desired behaviors returned with the initial protocol. This study was in the classic style of applied behavior analysis using an ABA reversal design.

Further studies (1979) using the same blind ABA design with SMR enhancement and theta suppression were undertaken by Shouse and Lubar with more children. Lubar noted a decrease in hyperactivity with reduced theta and increased SMR, with less of an effect on attentiveness. Again, the effects were reversible, showing statistically significant changes dependent on the stage of the design.

Six children were provided with long-term biofeedback and academic treatment for attention deficit disorders. Their symptoms were primarily specific learning disabilities, and in some cases, there were varying degrees of hyperkinesia. The training consisted of two sessions per week for 10–27 months, with a gradual phaseout. Feedback was provided for increasing either SMR activity at 12–15 Hz or beta activity at 16–20 Hz. Inhibit circuits were employed for blocking the SMR or beta when gross movement, excessive EMG, or theta (4–8 Hz) activity was present. Treatment also involved combining the biofeedback with academic training, including reading, arithmetic, and spatial tasks to improve attention.

All children increased SMR or beta and decreased slow EEG and EMG activity. Changes could be seen in their power spectra after training in terms of increased beta and decreased slow activity. All six children demonstrated considerable improvement in their schoolwork in terms of grades or achievement test scores. None of the children are currently on any medications for hyperkinetic behavior. The results indicate that EEG biofeedback training, if applied comprehensively, can be highly effective in helping to remediate children who are experiencing attention deficit disorders.

There have been several studies of ADHD and EEG biofeedback with and without medication. Monastra, Monastra, and George (2002) studied 100 children ages 6–19 who were diagnosed with ADHD, either inattentive or combined types. They examined the effects of Ritalin, EEG biofeedback, and parenting style on the primary symptoms of ADHD. This was a 1-year study that included participation in a multimodal outpatient program comprised of Ritalin therapy, parent counseling, and academic support at school (either a 504 Plan or an IEP).

Fifty-one of the participants received EEG biofeedback therapy. Post-treatment measures with and without stimulant therapy were conducted, indicating significant improvement on the Test of Variables of Attention and the Attention Deficit Disorders Evaluation Scale when participants were tested while using Ritalin. However, only those who had received EEG biofeedback sustained these gains when tested without Ritalin. Of

particular interest are the results of the qEEG Scanning Process (Monastra et al., 1999), which revealed a significant reduction in cortical slowing only in patients who had received EEG biofeedback. Similar studies evaluating neurofeedback in combination with and contrasting medications and metacognitive methods have had similar results (Fuchs, Birbaumer, Lutzenberger, Gruzelier, & Kaiser, 2003; Linden, Habib, & Radojevic, 1996; Thompson & Thompson, 1998).

For ADHD, operant conditioning by neurofeedback rests on the same well-established neurophysiological principles that mediate the effects of psychotropic medication. In neurofeedback, the patient learns to exert neuromodulatory control over the circuitry mediating the attentional process. If neurofeedback is to make effective and lasting changes in neural circuitry mediating attentional functions, those circuits must be adjustable by feedback control as well as able to maintain those adjustments over time; that is, the systems involved must have sufficient plasticity.

A good deal of research suggests that the prefrontal cortex and several centers in the limbic system should be included in any outline of attentional processes. It has been suggested that neural networks mediating attentional processes can be adjusted through neuromodulation and stabilized through long-term potentiation (LTP) into stable (attractor) states. It has been further suggested that during neurofeedback for ADHD, the patient consolidates an enhanced capacity to regulate state changes and gatings of signals between brain centers such that attentional capacity is enhanced. It has been argued that this process yields long-lasting results compared to stimulant medication treatment of ADHD, because it employs the same sort of neuromodulatory control and LTP that, with practice, indelibilizes such sensorimotor skills as riding a bicycle (Abarbanel, 1995).

In more recent times, methods are directed toward demonstrating the neurophysiological effects of neurofeedback through neuroimaging techniques. Lévesque, Beauregard, and Mensour (2006) conducted research using fMRI to evaluate the neural substrates affected by neurofeedback training. Fifteen subjects were randomly assigned to the treatment group and completed 40 sessions of neurofeedback following Lubar's (1997) protocol, in which the first 20 sessions increased SMR and decreased the amplitude of theta, and the second 20 sessions utilized standard theta/beta training (inhibiting theta while simultaneously increasing low beta). They utilized pre- and post-treatment parent rating scales (CPRS-R), digit span, and the integrated visual and auditory continuous performance test (IVA) for behavioral measures and the aforementioned counting Stroop task for fMRI measures. These measures

showed a significant reduction in symptoms following neurofeedback. The fMRI data indicated increased activity in the right anterior cingulate and left caudate nucleus.

This study demonstrates that neurofeedback influences limbic and subcortical structures, and it provides further evidence that these structures have a specific function in regulating attention and behavior. Furthermore, it provides functional knowledge about the brain and attention. It is very important to our understanding of the neurologic components and for the development of a concise definition of attention—which we currently lack—and we believe this to be a primary reason for our clear conceptualization of ADHD.

Like many studies in the neurofeedback literature, this study has its limitations. These include small sample size, lack of blinding to treatment condition, and lack of an active control condition. Nevertheless, current studies are underway, including those funded by NIH, to address these weaknesses.

In one recent well-designed German study, for example, researchers recruited 102 eight- to twelve-year-old children with ADHD (Gevensleben et al., 2009). They randomly assigned them to either 36 sessions of neurofeedback training or 36 sessions of computerized attention training, the latter of which acted as the control condition. The parents and teachers were also blinded as to the treatment condition. Parent and teacher ratings of ADHD symptoms and comorbid behavioral problems were obtained pre- and post-treatment.

Parent and teacher ratings indicated that improvements in the neurofeedback group were superior to those of the control group. Neurofeedback was also associated with greater reductions in parents' ratings of oppositional and aggressive behavior. The results from this randomized controlled trial of neurofeedback confirm that neurofeedback is an efficacious treatment for ADHD in children.

In an ideal design, control subjects would be provided with sham neurofeedback that was not linked to their actual EEG activity. If group differences were found with this procedure, it would be a clear indication that the specific EEG training received by experimental subjects, rather than any type of placebo effect, is what caused the improvements. As mentioned above, there are studies currently underway that are funded by the NIH to meet these very strict criteria.

LORETA Neurofeedback

Low-resolution electromagnetic tomographic neurofeedback (LNFB) was designed in 2003 by Marco Congedo. In this section we will describe the procedures

and rationale for LNFB with data from one published work and a recent study relevant to ADHD. Our most recent work deals with executive attention and the relationship between the anterior cingulate gyrus and dorsolateral prefrontal cortices.

It is necessary to provide an operational definition of attention, which has, to some extent, been evasive since William James posited that “everyone knows what attention is.” In our work, we operationalized attention as a specific sequential cerebral directive for reduction of sensory responses to or from competing streams of exogenous and endogenous stimuli in order to facilitate the encoding and subsequent storage of a stream or streams of interest for a potential or immediate selective or best response. This operational definition includes those variants of attention discussed by other authors and researchers, including focused, selective, visual, auditory, and tactile variants. Attention is inherently important and necessary to the overall executive functioning of the individual, and disruptions in brain mechanisms associated with attentive processes influence other cognitive processes and vice versa.

LORETA is an inverse solution for estimating cortical electrical current density originating from scalp electrodes through the use of optimal smoothing in order to estimate a direct 3-D solution for the electrical activity distribution. This method and the standardized version (sLORETA) compute distributed electrical activity within the cerebral volume, which is discretized and mapped onto a dense grid array containing sources of electrical activity at each point in the 3-D grid. This methodology produces a low-error solution for electrical source generators and provides statistical maps modeling distribution currents of brain activity utilizing realistic electrode coordinates for a three-concentric-shell spherical head model co-registered on a standardized MRI atlas, which allows for a reasonable approximation of anatomical labeling within the neocortical volume, including the AC and hippocampus. LORETA is only one of many estimation methods utilized for potential source generators. However, it is the only source localization method available at no cost for research.

The studies conducted by our lab (Cannon, Lubar, Congedo, Thornton, Towler, & Hutchens, 2007; Cannon et al., 2009) have thus far involved between 20 and 30 training sessions for different groups and individual subjects. Many neurofeedback providers use 30-minute rounds or hour-long sessions of feedback; however, spatial-specific neurofeedback training maintains that these are not realistic session lengths; in fact, it appears that the longer the round the more deleterious the results. These studies found that to be most beneficial, the training should be composed of four 5-minute train-

ing rounds with pre-session and post-session 3-minute eyes-closed and eyes-open baselines. LNFB has followed standard protocol in all studies designed to improve attentional processes by training individuals to increase 14–18 Hz (low-beta) power activity in one of four regions of training (ROTs) (see Exhibits 29.1 and 29.2).

Figure 29.2 shows each ROT for each of the studies conducted and the population of subjects. The left and right ACs total 7 voxels, the left prefrontal ROT contains 3 voxels, and the right prefrontal ROT totals 5 voxels. In a preliminary session, the participants are instructed to control tongue and eye movements, eye blinks (EOG), and muscle activity from forehead, neck, and jaws (EMG). This enables the subjects to minimize the production of extracranial artifacts during the sessions. It also provides an evaluation of the subject’s ability to score a minimum of 10 points per minute by meeting the reward criteria for increasing current density at the ROT and decreasing 1–3 Hz the range in which eye movements occur in a linear combination of 6 frontal leads and decreasing 35–55 Hz the range in which most muscle artifacts occur in a linear combination of 6 occipital and temporal leads.

At the end of the preliminary session, the participants are informed of the inhibitory and reward aspects of the training. Standardized thresholds are then set and maintained for each participant. The participants are provided visual and auditory feedback, and they are rewarded one point when they are able to simultaneously maintain all conditions for 0.75 seconds. The auditory stimulus provides both positive and negative reinforcement: an unpleasant “splat” sound when the conditions are not met, and a pleasant tone when they are. Similarly, the visual stimulus (e.g., a car or a spaceship driving faster and straighter) is activated when the criteria are met. Alternatively, a slower car driving in the wrong lane or the spaceship flying slow and crooked is activated when the criteria are not being met. Participants can see the score in a small window of the game screen.

The effects of LNFB in normal subjects in the first three studies showed a mean increase of approximately 11 points in working memory and processing speed scores on the third edition of the Wechsler Adult Intelligence Scale. These increases were significant, leading to the conclusion that LNFB positively influenced these two cognitive-behavioral processes.

LORETA neurofeedback training is difficult. However, the subjects do appear to be able to learn to regulate or increase low beta power in the anterior cingulate and associated cortical regions. We will discuss learning curves in normal subjects, followed by preliminary results for monozygotic twins concordant for ADHD (inattentive type). The second study we conducted

involved eight normal participants. Figure 29.3 shows the learning curve over 33 sessions of LORETA neurofeedback training; this trend is significant. The more interesting results were the significant learning effects of training the AC in the right and left prefrontal cortices and right somatosensory area (BA 40).

Attention deficit disorders are probably the most researched of the *DSM-IV* disorders, and there is substantial research demonstrating the positive results of neurofeedback as an alternative to pharmacological treatments. We recently utilized LORETA neurofeedback in monozygotic twins concordant for ADHD with mainly inattentive features. The subjects were two 24-year-old males diagnosed at age 12. Neither of the subjects had been on medications since age 14. It is possible to examine the effects of LNFB in numerous cortical regions and to gather information about the function of both region and frequency in the brain during this training. We will briefly discuss some of the results of this training in these two subjects.

We followed the standardized protocol used for all subjects for reward and inhibit criteria. Twin 1 completed 30 sessions, and Twin 2 ceased after 15 sessions. The limitation to this work is that we did not take pre- and post-treatment psychometric measures; however, this work was more concerned with neurophysiology and frequency-specific interactions between cortical regions. Figure 29.4 shows the learning curves for these subjects over training sessions.

Of particular interest is the learning effect in the AC without the interactions shown in controls; the cognitive division of the AC in these subjects shows limited effects in other regions of the cortex—specifically subgenual regions of AC and orbitofrontal cortex and left parietal regions. Figure 29.5 shows the comparisons for the training rounds between these twin subjects and normal controls. The results are similar to those of Bush, discussed earlier in the chapter. The regions of maximal increase are the bilateral insular cortices—with the higher increase occurring in the left insula and increases in the subgenual and posterior cingulate. We plan to continue this line of research in several disorders, including ADHD, substance use disorders, depression, anxiety, pain, and dementia.

LORETA neurofeedback offers some additional benefits compared to traditional neurofeedback methods in that it is possible to influence regions in the cortex not typically accessible from topographical EEG training alone. It also provides detailed information about frequency and functional interactions that can enhance our knowledge base. Most importantly, it reveals important information about neural pathways relative to both normal processes and pathology. No longer are we constrained to developing research studies to show that neurofeedback is effective. LORETA neurofeedback is one example of how we are using new technologies to better classify and predict what works for whom.

CONCLUSIONS

There are considerable challenges to neurofeedback that must be met in order to appease its critics. First, we must develop more rigorous methods for conducting research that controls for the demand characteristics of studies, specifically, pre- and post-treatment measures, diagnostic groups, rating scales, and protocols for the neurofeedback procedures. These types of studies are often difficult and require a great deal of time and financial support, which is slowly becoming available and hopefully will increase as the field progresses.

It seems inevitable that as the research and technology continue to improve, neurofeedback will be widely recognized as a valuable tool for improving human well-being. Our hope is that readers now have a better appreciation for the power of the human brain to change itself through the use of modern computer technology. We also hope to broaden awareness of this underutilized tool. It is only through continuing research, education, and increased awareness that research-supported treatments can be made available to those whom would otherwise remain untreated.

FOR ADDITIONAL TRAINING AND EDUCATION ON NEUROFEEDBACK

The International Society for Neurofeedback and Research Web site (<http://www.ISNR.org>) maintains a list of the most relevant neurofeedback papers published in peer-reviewed journals. There have been hundreds of papers published, including multiple controlled studies on ADHD alone. The comprehensive neurofeedback bibliography on the Web site lists them in topical groups. For certification information, visit <http://www.BCIA.org>.

Electroconvulsive Therapy, Transcranial Magnetic Stimulation, and Vagus Nerve Stimulation

Mansoor Malik

Ziad Safadi

Maria Hipolito

The last few decades have witnessed a rapid growth of novel ways to treat psychiatric illnesses. It is now possible to stimulate the cortical and subcortical structures of the brain directly through electric stimulation and thus modulate mood, behavior, and higher cortical functions. Of course, brain stimulation is not new to the field of mental health. Electroconvulsive therapy has been an effective treatment tool in psychiatry for nearly 70 years. In fact, Hippocrates noticed two millennia ago that insane patients showed decreased symptoms after having seizures by malaria. Though Paracelsus induced seizures by camphor, the use of therapeutic seizures was first introduced by Manfred Sakel in 1927. Chemical stimulation of the brain gave way to direct electrical stimulation of the brain through electroconvulsive therapy (ECT). This in turn has been followed up by transcranial magnetic stimulation (TMS), which involves the use of strong magnetic fields to generate electrical current in the brain, according to Maxwell's laws of electromagnetism. Other techniques of brain stimulation include vagal nerve stimulation, deep brain

stimulation, and magnetic seizure therapy. This chapter will provide an overview of these techniques and their clinical applications.

ELECTROCONVULSIVE THERAPY

At the beginning of 20th century, there was a greater enthusiasm for understanding the physical causes of mental illness. In this context it was noted (erroneously) that epilepsy and psychosis have an inverse relationship. In 1930, Sakel used newly discovered insulin to induce coma in patients with schizophrenia. This was followed up by von Meduna, who used camphor and many other substances to induce so-called chemical seizures. In 1937, two Italian physicians, Ugo Cerletti and Lucio Bini, used electricity for the first time to induce seizures in a homeless individual with schizophrenia, who showed dramatic improvement. Significant improvements in the technique of ECT have been made since then, including the use of synthetic muscle relaxants such as

succinylcholine, anesthesia for patients with short-acting agents, pre-oxygenation of the brain, electroencephalogram (EEG) seizure monitoring, and better devices that use sine waves.

ECT has been sufficiently refined so that it is a safe and effective procedure. However, it continues to be underutilized. The popularity of ECT has steadily declined since 1970 due to various misconceptions and myths about ECT and its effects on the brain. This has been fueled by widespread inflammatory misinformation about ECT in the popular media—for example, the 1962 novel written by Ken Kesey entitled *One Flew Over the Cuckoo's Nest*, which was later made into a very successful movie. Despite the bad publicity, ECT remains one of the most effective treatments for severe, life-threatening depression, refractory psychosis, and mania. ECT is gradually regaining the recognition and respect it deserves.

Electrophysiological Principles

The basic principle that governs ECT is Ohm's law, which states that the electric current is directly proportional to the voltage across two points and inversely proportional to the resistance. Dosage of electricity used in ECT is very small, typically only about 100–500 millicoulombs. While the brain has very low electrical resistance, the skull has very high electrical impedance. About 20% of the current used actually gets into the brain and causes seizures by the propagation of action potentials by causing neuronal depolarization.

Positron emission tomography (PET) studies have shown that during the ECT procedure, there is an increase in the permeability of the blood-brain barrier and brain metabolism. This is followed by a decrease in blood flow and metabolism, especially in the frontal lobes. Studies show that metabolic changes are correlated with clinical response of ECT.

ECT Procedure and Technique

ECT is usually performed 2–3 times a week under general anesthesia. It can be given with unilateral or bilateral electrode placement. Though bilateral placement is associated with superior clinical response, unilateral placement may have fewer cognitive effects. Length of treatment is governed by clinical response, and most patients require between 8 and 12 ECT treatments.

Seizure during ECT is monitored by EEG tracing. For an effective response, a seizure should continue for about 30–60 seconds. Seizure threshold varies widely across individuals, so it is important to measure the seizure threshold and titrate the dose accordingly. Most

physicians use 2.5 times the dose of seizure threshold for unilateral electrode placement.

Although there are no absolute contraindications to ECT, and mortality secondary to ECT is comparable to that of anesthesia induction, use of ECT requires careful evaluation and attention to the details of informed consent issues. Relative contraindications include presence of a space-occupying lesion, recent cerebral hemorrhage or stroke, severe cardiopulmonary disease, and unstable vascular aneurysms.

Indications for ECT

ECT remains the treatment of choice for severe, debilitating, life-threatening depression, especially when it is associated with psychotic symptoms; in such circumstances, ECT can be considered the first line of treatment. Other indications include bipolar disorder, both the manic and depressed phases, and acute schizophrenia (catatonic or disorganized forms show greater response). ECT can also be effective for treating obsessive-compulsive disorders, delirium, neuroleptic malignant syndrome, tardive dyskinesia, and chronic pain syndromes. Contrary to the common belief, ECT is safe and effective during pregnancy and actually has fewer harmful fetal effects than commonly used psychiatric medications.

Adverse Effects of ECT

ECT is misleadingly associated with permanent brain damage in common folklore and negative propaganda. However, this topic has been extensively reviewed and there is no evidence that ECT causes any brain damage. In fact, there is no evidence even from animal studies that ECT without anesthesia and at a frequency and dose higher than those used in clinical practice causes any neuropathological changes (Weiner, 1984).

Memory impairment is by far the worst adverse effect associated with ECT. For most patients this memory loss is limited to short-term retrograde and anterograde amnesia, which can stretch back or into the future for a few hours to a few days. Such amnesia is usually not very troublesome; however, ECT can be associated with permanent loss of memory of personal events such as important dates in one's life. Some patients complain of holes in their memory going back several years or even decades after ECT. In some patients, ECT is associated with permanent long-term anterograde amnesia.

Efficacy for Depression

In a systematic review, Gabor and Laszlo (2005) found ECT treatment to be significantly more effective in the

treatment of depression than simulated ECT (9 studies, 321 patients) or antidepressant drug treatment (14 studies, 1,081 patients).

Kho, van Vreeswijk, Simpson, and Zwinderman (2003) carried out a meta-analysis comparing ECT with medications and simulated ECT in the treatment of depression. They identified 15 controlled trials. Overall, ECT was shown to be superior to medication and simulated ECT. Some evidence was found that psychosis predicted better response to ECT. The funnel plot showed the absence of publication bias. There was no exaggeration of effect size in the lower-quality trials. No evidence was found for superior speed of action of ECT or for a difference in efficacy between sine-wave and brief-pulse stimulation.

The UK ECT Review Group (2003) also carried out a large meta-analysis and included observational studies with randomized controlled trials (RCTs). They found that real ECT was significantly more effective than simulated ECT (6 trials; 256 patients; standardized effect size [SES] = -0.91 ; 95% CI: -1.27 , -0.54). Treatment with ECT was significantly more effective than pharmacotherapy (18 trials; 1,144 participants; SES = -0.80 ; 95% CI: -1.29 , -0.29). Bilateral ECT was more effective than unipolar ECT (22 trials; 1,408 participants; SES = -0.32 ; 95% CI: -0.46 , -0.19).

Efficacy in Schizophrenia

Results for ECT treatment in schizophrenia are less clear than in depression. Overall the results are mixed. In a large meta-analysis done by the Cochrane schizophrenia group, Tharyan and Adams (2005) found that ECT combined with treatment with antipsychotic drugs may be considered an option for schizophrenia, particularly when there is a limited response to medications (treatment resistance) or when rapid global improvement and reduction of symptoms are desired. They included 26 randomized trials in their study. When ECT was compared with placebo or sham ECT, the ECT group clearly fared better ($n = 392$, 10 RCTs; (Risk Ratio) RR = 0.76 ; random (Confidence Interval) CI: 0.59 , 0.98 ; (Number Needed to Treat) NNT = 6 ; CI: 4 , 12). There was a suggestion that ECT resulted in fewer relapses in the short term than sham ECT ($n = 47$; 2 RCTs; RR fixed = 0.26 ; CI: 0.03 , 2.2), and a greater likelihood of discharge from hospital treatment earlier than those treated with sham ECT ($n = 495$; 14 RCTs; RR fixed = 0.71 ; CI: 0.33 , 1.52). However, there was no evidence that this early advantage for ECT is maintained over the medium to long term.

Efficacy in Bipolar Disorder

ECT is generally considered an effective treatment for refractory mania and bipolar mixed states. However, in a review of ECT for the treatment of mixed states, Valenti et al. (2008) could only find three randomized trials. They concluded that ECT is an effective, safe, and probably underutilized treatment of mixed states.

Sienaert and Peuskens (2006) reported a case series of six patients with mania that was refractory to antipsychotic and mood-stabilizing medications. All the patients responded regardless of whether or not they had any symptoms of psychosis.

Conclusion

ECT is a safe and effective treatment. It is significantly underutilized in the United States. Despite commonly held beliefs, there is no evidence that it causes permanent brain damage. It can be associated with memory impairment; however, given the significant morbidity and mortality of severe depression, these adverse effects might outweigh the overall benefits of ECT.

VAGAL NERVE STIMULATION

As its name indicates, vagal nerve stimulation (VNS) is the modulation of higher cortical functions through electrical stimulation of the afferent vagus nerve. Afferent connections of vagus nerve to various areas of the cortex and limbic system through nucleus tractus solitarius are well known from anatomical studies. This, along with the relatively easy surgical access of the vagus nerve through the neck, stimulated interest in the possibility of electrically stimulating the vagus nerve to understand the impact on limbic and cortical functions.

As early as 1938, Bailey and Bremer reported that VNS in a cat elicited synchronized activity in the orbital cortex. In 1949, MacLean (1990) stimulated the vagus nerve and recorded electroencephalograms from the cortical surface of anesthetized monkeys and found inconsistent slow waves generated from the lateral frontal cortex. Dell and Olson (1951) found that VNS evoked a slow-wave response in the anterior rhinal sulcus and amygdala of awake cats with high cervical spinal section. Finally, Zabara (1985) demonstrated the anticonvulsant action of VNS in experimental seizures in dogs. Penry and Dean (1990) and others (Rutecki, 1990) used VNS with the first human implant for the treatment of epilepsy in 1988.

In 1997, the U.S. Food and Drug Administration approved the use of VNS as an adjunctive therapy for

partial-onset epilepsy. In 2005, the FDA approved the use of VNS for refractory depression.

Rationale for Use in Depression

Vagal nerve stimulation was initially used for treatment of epilepsy. Several anticonvulsant medications, including carbamazepine, lamotrigine, and valproate, are used as mood stabilizers and/or antidepressants in bipolar disorder. Conversely, ECT also has anticonvulsant properties. Neuroimaging studies in epileptic and depressed patients have provided evidence that VNS alters activity in the thalamus and cortex, including the ventromedial prefrontal and orbital cortices (Chae, Nahas, Lomarev, Denslow, Lorberbaum, Bohning, & George, 2003). These regions are thought to be important in mood regulation (Drevets, Bogers, & Raichle, 2002). Similarly, neurochemical studies in animals and humans revealed that VNS modifies concentrations of monoamines in the central nervous system (the transmission of serotonin, norepinephrine, GABA and glutamate, and neurotransmitters associated with the pathophysiology of depression; Dorr & Debonnel, 2006). All these findings paved the way for use of VNS for refractory depression.

Techniques for Application

VNS is a surgical procedure that can be done on an outpatient basis. It is carried out by a neurosurgeon or a vascular surgeon and can be compared with cardiac pacemaker implantation. The procedure involves the placement of a subcutaneous pulse generator in the chest wall. The electrodes are placed over the left vagus nerve through an incision in the neck. The leads connecting the generator and electrodes are tunneled under the skin. The whole procedure takes about 2 hours.

The pulse generator can be programmed externally with respect to current amplitude, pulse width, frequency, and inter-train interval. In addition, the patient is given a magnet that is used to stop the generator temporarily when it is placed over the generator.

Efficacy for Depression

During the clinical trials of VNS for epilepsy, several investigators noted mood improvements in their patients (Ben-Menachem et al., 1994; Handforth et al., 1998). Although decreased seizure frequency likely accounted for some of these improvements, the benefits went beyond those attributable to improved seizure control. For example, some patients with minimal or no improve-

ment in seizure frequency reported substantial improvements in mood.

Subsequently, a prospective study of patients with epilepsy showed a trend toward mood improvements, based on the Cornell Dysthymia Rating Scale (Harden, Pulver, Nikolov, Halper, & Labar, 1999). Since that time there have been a number of open naturalistic studies that used VNS as an add-on treatment for refractory depression and demonstrated some benefit.

Daban (2007) carried out a systematic review and found 98 references in the literature to VNS use for treatment-resistant depression. However, they only included 18 studies in their review because of quality and methodology issues. Out of these, 6 were short duration (10 weeks) and 12 were of longer duration (11–24 months). Overall the results from most of these studies noted a positive trend for the use of VNS for depression; however, in the absence of randomized trials, no firm conclusions can be drawn.

So far only one double-blind study has been used for commercial registration of VNS (Rush, Sachem, et al., 2005). This was a 10-week study that compared active and sham VNS in a group of treatment-resistant depressed patients ($n = 222$, active = 112, sham = 110). There were no differences between the primary outcome scores on the Hamilton Rating Scale for Depression (HRSD) at 10 weeks (reduction: active = 15.2%, sham = 10%, $p = 0.25$). However, there was significant difference in the secondary outcome measure, the Inventory of Depressive Symptomatology–Self-Report ($p = .032$).

In a large multicenter trial, George et al. (2005) found a sustained response with VNS for treatment-resistant depression. They found that the average change after 12 months in the group that received add-on VNS was much higher (-8.2 ± 9.1) than in the control group (-4.9 ± 7.8 ; $p = 0.006$). There was a doubling of benefit between 3 and 12 months, suggesting progressive benefits.

Overall it appears that although only a minority of treatment-resistant depression patients respond to VNS, there is a good possibility that the effect will be robust and persistent in responders (Fitzgerald & Daskalakis, 2008). This is supported by the pivotal studies done for commercial registration by the manufacturer (Cyberonics). In both of these studies, there was significant increase in response/remission when patients were examined 9 months after the implantation (Rush, Sachem, et al., 2005). Subsequently long-term clinical outcome for these patients was compared in a companion economic study. Across a variety of clinical measures, there was a substantial difference in long-term clinical outcomes favoring the VNS group.

Adverse Effects

The most common side effects of VNS include voice alteration, coughing, neck pain, and dyspnea (Marangell, Rush, & George, 2002). Tolerance to these side effects develops rapidly, and frequency of these effects decreases considerably in the long-term treatment. Moreover, the use of an on-demand magnet gives the patient acute control of side effects by allowing him or her to temporarily discontinue the stimulation.

Though to the onset of mania is a concern in the VNS, only three studies have evaluated this. In the study by Rush et al. (2005), three patients met the *DSM-IV* criteria for mania while receiving VNS. In the case of one of these patients, the stimulation was stopped during the episode. In two of the studies, no significant changes regarding manic symptoms were seen.

The side effects reported in long-term studies are generally the same as those reported in short-term studies. They are typically mild and restricted to the time of the stimulation. There is no evidence the VNS causes adverse cognitive effects.

TRANSCRANIAL MAGNETIC STIMULATION

The principle of inductive brain stimulation with eddy currents has been noted since the 19th century. Magnetic stimulation was first used to elicit behavioral changes by d'Arsonval at the end of 19th century. He elicited phosphenes (perception of light flickers by stimulation of the occipital cortex); however, he was limited by his equipment, which only allowed for production of low-intensity magnetic fields. It was not until 1985 that Barker and his colleagues in Sheffield, in the United Kingdom, developed a device capable of inducing magnetic fields strong enough to depolarize the motor cortex. He proposed the use of transcranial magnetic stimulation for clinical purposes. Initially it was used for various neuromuscular disorders and brain mapping by neurologists. The observed behavioral effects during these trials suggested that it might have an antidepressant effect. This led to the first clinical trials of TMS for depression in Europe with a round coil device in the early 1990s. Two open studies with round coils were carried out to deliver TMS therapy over the vertex to treat depression; however, the antidepressant effect was not robust (Grisaru, Yarovslavsky, Abarbanel, Lamberg, & Belmaker, 1994). George and Wasserman (1994) suggested that the prefrontal and limbic regions were more

important for mood regulation than the brain regions near the vertex. This was supported by the fact that ECT works only when applied over the prefrontal regions. Thus the first open trial of prefrontal TMS therapy for depression was performed in 1995. Since that time, multiple clinical trials have supported the use of TMS for depression and some other psychiatric disorders.

Physical Principles Behind TMS

Two physical principles form the basis of TMS. The first is Ampere's law, which relates the integrated magnetic field around a closed loop to the electric current passing through the loop. The second is Faraday's law of magnetic induction, which states that the induced electromotive force in any closed circuit is equal to the rate of change of the magnetic flux through the circuit. These two principles are employed sequentially during the TMS procedure. First an alternating current is passed through an insulated metal coil around the skull. Typically the electrical energy stored in a capacitor is discharged into the coil with a peak current of about 3,000 amps. This generates a magnetic field perpendicular to the flow of the current in the coil. This rapidly changing magnetic field (typically ~12–15kT/s) penetrates the scalp and induces a weak electric field within the brain over a localized region near the cortical surface. The strength of the induced current depends on the rate of change of the magnetic field. The stimulators and coils currently in use are thought to activate neurons at a depth of 1.5–2 cm beneath the scalp (Epstein, Figiel, & McDonald, 1990). This creates a localized area of depolarization and induces current flow in a localized brain loop. Though direct effects of TMS are localized to the cortex, distal brain areas can be affected trans-synaptically, as evidenced by PET studies on subcortical areas (Kimbrell et al., 1999).

Techniques of Stimulation

The number of electrical pulses that can be delivered during TMS is limited by the charging rate of the capacitors that store the electrical charge. Initially single pulse magnetic stimulators that could only produce electrical pulses every few seconds were used. This was called single-pulse TMS. However, now stimulators using multiple capacitors can generate pulses up to 60 Hz. Thus repeated TMS (rTMS) has become the standard in clinical research. rTMS, as opposed to single-pulse TMS, can increase or decrease the excitability of cortico-spinal or cortico-cortical pathways, depending on the intensity of stimulation, coil orientation, and

frequency of stimulation. The mechanism of these effects is not clear, although it is widely believed to reflect changes in synaptic efficacy akin to long-term potentiation and long-term depression (Fitzgerald, Huntsman, & Gunewardene, 2006). TMS at 1 Hz is referred to as low-frequency TMS and is associated with a reduction in the local brain activity (Chen & Seitz, 2001)

Various types of coils such as round coils, figure-eight coils, and H-shaped coils, are currently used for TMS. The relative merits of these coils are unclear and depend on the manufactures.

A commonly used rule during TMS procedure is "the rule of five." It is used to identify the left dorsolateral cortex, which is the main site of stimulation for TMS. First the area of the scalp overlying the motor cortex is identified through demonstration of the motor evoked potential (MEP). This is identified by the contraction of the thumb muscle (abductor pollicis brevis) when the TMS coil is applied over it. Then the TMS coil is advanced by 5 cm in the parasagittal plane and is placed over the left dorsolateral prefrontal cortex (LDLPC). This description is not exact but gives a very good approximation of the method.

Mechanism of Action

TMS directly stimulates only a small region in the cortex and does not produce direct electrical stimulation in more distal brain regions. Due to the cortex's massive interconnections and redundant cortical-subcortical loops, TMS is thought to affect the limbic system, which probably explains the mood changes secondary to TMS.

TMS has been combined with functional neuroimaging such as PET and fMRI in order to investigate this hypothesis. Strafella, Paus, Barrett, and Dagher (2001) used PET to show that prefrontal cortex TMS causes dopamine release in the caudate nucleus and has reciprocal activity with the anterior cingulate gyrus. TMS therapy in the lateral prefrontal cortex has been shown to cause changes in the anterior cingulate gyrus and other limbic regions in depressed patients (Schule et al., 2003). Similarly Teneback et al. (1999) have shown that left prefrontal TMS therapy produces immediate blood-flow increases in the orbitofrontal cortex, hippocampus, and left prefrontal cortex.

Blood-flow changes in prefrontal and paralimbic areas have been associated with improvement in depressive symptoms (Catafau, 2001). Overall brain-imaging studies seem to indicate that TMS has effects in important subcortical limbic regions, which are involved in mood and anxiety regulation.

Cellular mechanisms involved in long-term potentiation and long-term depression have been postulated to be the underlying mechanism for rTMS (Wang, 1996), as these mechanisms mediate the long-term changes that outlast the duration of stimulus.

Similarly, animal studies in monkey and rodent models have reported antidepressant-like behavioral and neurochemical effects secondary to TMS. Reduction in immobility time in the Porsolt forced swimming test (the most commonly used test for assessment of depression in animal models) has been demonstrated by application of rTMS in animal models (Belamker & Grisaru, 1998). Significant up regulation of beta adrenergic receptors in the frontal cortex has been reported as well Ben-Shachar, D., Gazawi, H., Riboyad-Levin, J., & Klein, E. (1997).

Effect in Depression

Over 40 controlled trials have compared TMS with sham TMS in the treatment of depression. A greater number of open trials have also been conducted. Sample sizes in these trials are small, typically 5–10 patients. Burt et al. (2002) carried out a meta-analysis of sham and other controlled trials with TMS. They included 23 studies and found that combined effect size (Cohen's D) was 0.67, indicating a moderately high effect size. However, the magnitude of the therapeutic effects was less clear. For example, the average percentage change in HRSD scores in all the studies was 23.8%, as opposed to the average change in HRSD scores for ECT, which can approach 70% (Sackheim, 2000)

Avery et al. (1999) randomized 68 patients with treatment-resistant depression to 15 sessions of active or sham rTMS. They reported statistically significant differences between active and sham treatments on the HRSD. The response rate of the active group was 30.6%, compared with 6.1% for the sham group.

O'Reardon et al. (2007) carried out a large double-blind trial of TMS and sham TMS across 22 sites in the United States, Canada, and Australia. This trial used a dose of stimulation much greater than that utilized in previous research in regard to both the intensity (120% of the resting motor threshold) and number of stimuli applied per day (75 trains). In this trial, 301 medication-free patients with major depression who had not benefited from prior treatment were randomized to active ($n = 155$) or sham TMS ($n = 146$) conditions.

These patients were initially randomized to an acute treatment protocol that could extend for up to 6 weeks with a 3-week rTMS taper period. The active group achieved a significantly greater reduction in depression than the sham group at 4 and 6 weeks on most of the

rating scales used in the study, although not in the primary outcome variable—the HDRS. This study showed substantial progressive improvement in the active treatment group over the entire 6 weeks of the study.

Overall, a number of randomized clinical trials and at least three misanalysis studies support the claim that active TMS is superior to sham TMS in patients with refractory depression (Burt, Lisanby, & Sackheim, 2002; Holtzheimer, Russo, & Avery, 2001; Martin, Barbanj, & Schlaepfer, 2002; McNamara, Ray, Arthurs, & Boniface, 2001). However, it has to be pointed out that not all studies show a superior response to TMS. At least three randomized trials failed to demonstrate a difference in response between active and sham TMS (Herwig et al., 2007; Loo, Mitchell, Sachdev, McDarmont, Parker, & Gandevia, 1999; Mogg et al., 2007).

Comparison with ECT

Though it was always hoped that TMS would be a benign version of ECT with all the clinical benefits and few side effects, the results so far have been mixed. Overall, TMS appears to be as effective as ECT in non-psychotic depression; however, ECT appears to be far superior in severe and psychotic depression. To date, there have been five clinical trials with head-to-head comparison of ECT and TMS. In the most recent trial, Eranti et al. (2007) randomized 46 patients to either a fixed 15-day course of left-sided rTMS or a course of ECT that was flexible in duration and mode of administration (uni- or bilateral). At the end of the acute treatment there was a significant treatment advantage for the ECT group compared with the rTMS group. Notably, the mean age of patients in this study was older than 60.

TMS Use in Schizophrenia

TMS has been proposed as a treatment for refractory auditory hallucinations. Various studies have utilized continuous 1-Hz TMS over the temporoparietal cortex to inhibit auditory hallucinations. Aleman, Sommer, and Kahn (2007) carried out a meta-analysis of these studies. They included 10 studies ($N = 212$). They found an effect size of 0.76 (95% CI: 0.36, 1.17). This seems to be a fairly robust effect; however, larger controlled trials are needed before definite conclusions can be drawn.

TMS Use in Pain and Migraine

Anti-nociceptive effects have been reported with TMS therapy with both motor cortex and prefrontal cortex stimulation. Many open studies suggest improvement

in chronic pain with TMS (Lefaucheur, Drouot, Menard-Lefaucheur, & Zerah, 2004). Defrin, Grunhaus, and Zamir (2007) reported on a double-blind controlled trial in patients ($n = 12$) with central pain after spinal cord injury. They found that although the TMS and sham groups had equal initial improvement in pain, only the TMS group showed a significant increase in pain threshold.

Brockardt et al. (2006) report on a controlled trial studying the effects of TMS on pain after bariatric surgery ($n = 20$). They found that with active TMS, there was a 40% reduction in the use of opioids in the first 48 hours after the surgery.

Individuals with migraine have been shown to have decreased phosphene threshold compared to controls during the TMS procedure. This led to the use of inhibitory TMS for migraines. There have been multiple reports of improvement in open studies. Khedr, Ahmed, and Mohamed (2006) et al. reported on a controlled trial ($n = 50$) in which TMS use was significantly more effective than the control (69% vs. 48%).

Safety and Adverse Effects

The biggest safety concern for TMS use is the induction of seizures. Eight seizure episodes have been reported with use of rTMS, all of which were self-limiting and none of which resulted in lasting physical sequelae (Wasserman, 2000).

Muscles and nerves near the TMS coil are activated and can result in muscle tension and headache in susceptible individuals, though it is rarely a problem in reality. Exposure to repetitive high-pitched sounds from the TMS coil can produce hearing deficits, and individuals undergoing therapy wear ear plugs. Other potential adverse effects include cognitive disruption, scalp burns, and possible carcinogenic effects of prolonged exposure to magnetic fields.

TMS should be avoided by patients with cardiac conditions, especially individuals with pacemakers, women who are pregnant, and children. Presence of metal anywhere in the head is a contraindication, as it can be moved or heated by the TMS.

There has been a report of two cases of altered visual function (one improved, one worsened) in two patients receiving left prefrontal rTMS (1 and 5 Hz) in depression trials. Both patients had some form of baseline visual change and the TMS-induced effects resolved over days or weeks (Marcolin, Souza Filho, Teixeira, & Fregni, 2006). Finally, TMS can be associated with mania or hypomania. At least 13 such cases have been documented; most of these occurred in patients with

bipolar disorder (Xia, Gajawani, Muzina, Kemp, Gao, Ganocy, & Calabrese, 2007).

FDA Approval

After 3 years of review, FDA finally approved the TMS machine by the manufacturer Neuronetics for the treatment of major depressive disorder in adult patients who have failed to achieve satisfactory improvement from one prior antidepressant medication at or above the minimal effective dose. However, the availability of TMS is currently quite limited, and at the time of this writing, only a handful of clinical centers carry out this procedure.

CONCLUSIONS

Brain stimulation is an effective treatment modality that is still underutilized. Research on various forms of brain stimulation techniques is rapidly progressing. However, there still is a great need to improve awareness of these effective treatments both in the consumer and psychiatric provider sectors. ECT should be considered an alternative treatment option early on in severe life-threatening depression rather than a last resort. Similarly, both TMS and VNS should be presented to patients as an alternative if depression is not responding to adequate trials of medication and psychotherapy. Unfortunately, expertise in the administration of brain stimulation treatment is still limited. However, there are various ways to find facilities that administer these treatments. Professional associations such as the American Psychiatric Association (<http://www.psych.org>) and the Association for Convulsive Therapy (<http://www.act-ect.org>) can be useful sources of information and a referral base for locating practitioners in a specified area. The Association of Convulsive Therapy publishes the *Journal of ECT*, which is an excellent source of information on areas of interest in the field of brain stimulation.

Integrative Multimodal Assessment and Intervention: A Clinical Protocol

Roland A. Carlstedt

This chapter presents an integrative, conceptually based, and field-tested assessment and intervention protocol. It emanates, in part, from the high-risk model of threat perception (HRMTP; see chapter 9) and multiple longitudinal ecological investigations of personality, behavioral, and psychophysiological measures and their relationship to performance (Wickramasekera, 1988; Carlstedt, 2001b, 2004, 2007, 2008). It has evolved into a multi-procedural clinical approach the goal of which is to better illuminate mind-body dynamics at the intraindividual level. It is marked by a hierarchical diagnostic process that relies heavily on in-vivo, ecologically obtained, longitudinal, and repeated measures; data; and analyses to guide assessment and the selection and evaluation of interventions.

In contrast to clinical trials, upon which most practice approaches are based (group findings), the presented protocol (Carlstedt Protocol-Clinical; CP-C) is highly individualized and can be viewed as a clinical trial involving a single patient who serves as his or her own control not only to arrive at a diagnosis but, more importantly, to gain objective insight into actual underlying neuropsychophysiological processes and responses as they occur, to better justify or confirm a diagnosis that may have been based on limited information.

The use of procedural and methodological layers of increasing evidentiary value to reduce false-positive and negative test results, as well as determine the efficacy of an intervention, is central to the protocol. This latter pursuit is enhanced through an extensive pre- and post-intervention design that analyzes treatment procedures and modalities beyond the cursory.¹

INTEGRATIVE DIAGNOSIS: PATIENT-CLIENT EVALUATION

Assessment of HRMTP Primary Higher-Order Subject Variables

The first step of the CP-C involves determining a patient's constellation of HRMTP-PHO subject variables

1. "The cursory" would be having a weekly psychotherapy session with an anxiety patient but failing to ever consider and monitor autonomic nervous system measures that are manifested during panic attacks, let alone assessing changes in autonomic nervous system responses as a function of an intervention. A cursory approach assumes that a diagnosis is correct and an intervention is working; an integrative evidence-based approach attempts to document, verify, confirm, and support a diagnosis and conclusions regarding treatment efficacy.

(see chapter 9). These measures—hypnotic susceptibility (HS), neuroticism (N), and repressive coping (RC)—are assessed by specific tests of known validity and reliability. The Stanford Hypnotic Susceptibility Scale–C (SSHS; Weitzenhoffer & Hilgard, 1962) is used to measure HS. Tests of HS are behavioral tests that require special training to administer. Alternatively, the Tellegen Absorption Scale (TAS; Tellegen & Atkinson, 1974) can be used to assess components of absorption that are strongly correlated with HS (Kirsch & Council, 1992). The assessment of HS takes about 45 minutes and can be done at or prior to intake if the TAS is used in place of the SSHS scale. Individuals scoring 30 or above on the TAS usually test high for HS (Carlstedt, 2001b, 2004). The Eysenck Personality Inventory (EPI; Eysenck & Eysenck, 1975) is used to measure N, and although this test instrument originated decades ago, it was well validated and correlates highly with autonomic nervous system (ANS) measures that are associated with psychophysiological disorders. Alternative test instruments for measuring N include the Positive Negative Affect Schedule (PANAS; Watson, Clark & Tellegen, 1978) and the N scale of the Neuroticism-Extraversion-Openness test battery (NEO; Costa & McCrae, 1985). RC is measured by the Marlowe-Crown Scale (MC; Crowne & Marlowe, 1960). Although this test was originally designed to measure social desirability, it has been found to tap the tendency for repressive coping.

Scores on the three tests (HS, N, RC) result in a mind-body or primary higher-order (PHO) profile such as high-high-low (H-H-L), with the first descriptor revealing level of HS, the second N, and third RC. Raw scores corresponding to each measure can also be presented such as 29-20-5. Readers are referred to the reference list for more information on the accessibility, scoring, and psychometric properties of these tests. It should be noted that all the above instruments have been extensively validated (Carlstedt, 2001b).

A patient's PHO profile can provide important clues into mind-body and ANS response tendencies even when the patient has not actually been examined. Interactions of these measures, especially at the extremes of the distribution (high or low), predict numerous psychological tendencies and behavior, ANS reactivity, and intervention amenability and compliance (see chapter 2; see also Wickramasekera, 1988).

These tests should be routinely administered in medical and mental health settings and practices. However, since all measures based on self-report are fallible (false-positive and false-negative vulnerability) in an integrative approach, additional evidence should be sought to support initial diagnostic conclusions that

are based on a patient's PHO profile. While PHO profiles at the extremes (e.g., H-H-L or L-H-L) are reliable predictors of differential responding, false-positive and false-negative results can occur in the 10%–30% range, and although this points to the predictive potency of HRMTP PHO profiles, from an individualized perspective, group findings are only good or valid to the extent that an individual actually responds or behaves as would have been predicted on the basis of concurrent or objective mind-body measures (e.g., ANS measure of stress such as heart-rate variability). For example, an individual who has a PHO profile of H-H-L would be expected to have elevated neuroticism-driven ANS-SNS (sympathetic nervous system) reactivity at baseline. However, since false-positive and false-negative rates can approach 30%, it is always better to criterion reference assessment results that are based on self-report with measures that reveal underlying psychophysiological responding. Thus, a more direct method for assessing PHO profile response tendencies that constellations of HS-N-RC purportedly predict is measuring actual psychophysiological responding in the context of a validated laboratory office-based stress test.

Psychophysiological Stress Testing

Psychophysiological stress testing is routinely administered to all patients at intake. It provides an additional layer in the evidence hierarchy (Rosenthal, 2004) by extending self-report and behavioral measures to actual underlying mind-body responding. A stress test paradigm that has been extensively used and validated is a backward-counting task (Carlstedt, 2009) in which an individual is asked to count backward from 1,000 by seven (serial 7s in this paradigm; start and subtraction number vary across studies) for a period of 2 minutes while heart-rate variability (HRV) is monitored. A 2-minute baseline precedes and 2-minute control period follows the counting condition. HRV measures—most importantly, differences in HRV-ANS measures between the baseline and backward-counting task—are then compared. Figures 31.1 and 31.2 emanate from a client with performance anxiety disorder. His PHO profile is H-H-L, which would predict anxiety symptoms with increased SNS activation as a function of stress (S7s test as a stressor).

The measure that is most predictive of future responding to stress in real-world situations and settings is the LF/HF ratio reading (Carlstedt, 1998, 2004). This measure of autonomic balance, expressed as the ratio of low- to high-frequency ANS activity, tends to change differentially as a function of encountered stressors,

Figure 31.1 Baseline condition of the S7s backward counting task.

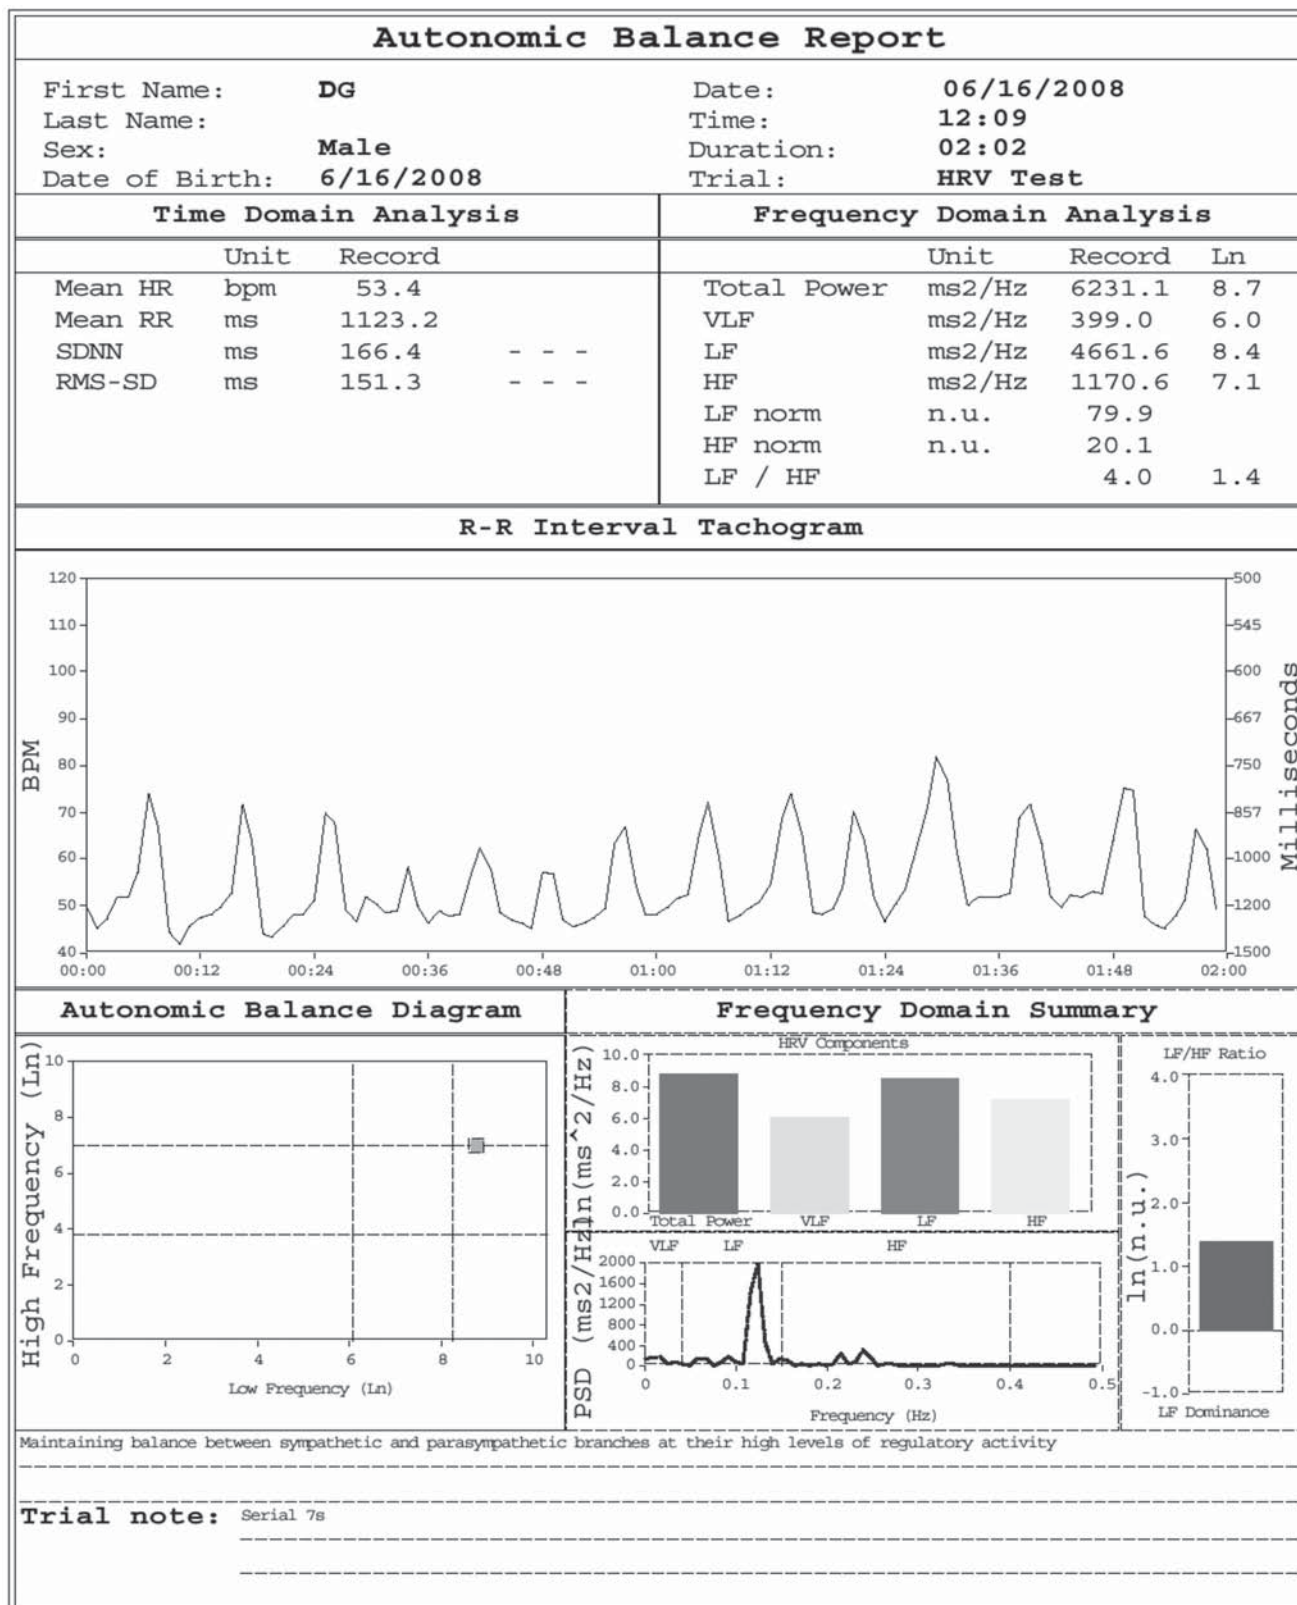

Figure 31.2 Backward counting condition of the S7s stress test.

especially cognitive challenges such as a novel arithmetic task like the serial 7s (S7s) backward-counting task. Mediating factors in the stress-response equation include PHO profile, in which high N is usually associated with increases in SNS activity, as reflected in more very low-frequency (VLF) activity and a greater LF/HF in the backward-counting task than at baseline. It is possible, on the basis of stress test responses, to predict extreme (high-risk) HRMTP PHO profiles (see chapter 9) with a high degree of accuracy, especially high N.

The S7s stress test can also be used to concurrently validate or criterion reference HRMTP self-report and behaviorally based test measures with independently derived psychophysiological ANS responses. It also serves to assess stress response tendencies in patients with more ambiguous HRMTP PHO profiles that are difficult to surmise or predict without further testing. In such cases, for example, a patient who scores M-M-M (middle-range scores for PHO measures), the S7s stress test result would be used to predict real-world stress response tendencies that could not be assumed based on this less transparent PHO profile. This particular individual's stress test responses were consistent with what one would have predicted on the basis of his HRMTP PHO profile, with a large increase in the LF/HF ratio occurring as a function of the serial 7s backward-counting task (from 2.7 to 4.0; see Figures 31.1 and 31.2).

Neurocognitive Testing

The two previous assessment and diagnostic tests serve a more global clinical purpose and predict mind-body responding and behavior across a variety of conditions and disorders that have strong anxiety components. By contrast, the third component of the CP-C battery serves to evaluate cognitive functioning and isolate deficits through the use of an Internet-based neuropsychological test battery called Web-Neuro (Brain Resource Company, 2009). This normed and validated battery is well suited as a screening instrument for ADD and cognitive and learning disorders. It can also be used in an ancillary manner to preliminarily assess the impact of head injury, depression, and psychophysiological disorders or cognitive functioning. Figure 31.3 depicts the functional and anatomical findings for a patient who was assessed with Web-Neuro. Standard neuropsychological tests are listed across the top of the figure, with regional localization of brain functioning (brain area and/or structure) running vertically on the left side).

The summary overview results (Figure 31.3) are elaborated in Figure 31.4 as deviations in performance (+ or -) scores relative to a normative database.

Quantitative EEG (qEEG, Brain Mapping)

In cases where red flags are raised in initial neurocognitive testing, clinicians can obtain greater insight into the functional mechanisms of more global deficits through quantitative electroencephalography (qEEG) or brain mapping micro-analyses of cortical functioning. qEEG uses the International 10–20 electrode placement system to reveal electrical activity that emanates from neurons in the brain close to the surface (under the skull; Niedermeyer & Lopes da Silva, 2004). Since the neuropsychological tests (see Figures 31.3 and 31.4) revealed various deficits, it may be important to use EEG, a measure of real-time responses to task demands and mental stressors, to more precisely evaluate brain functioning, and to better discern and delineate cortical mechanisms (functional and anatomical) that may be associated abnormal scores.

Figures 31.5, 31.6, and 31.7 show reports that are generated with the Brain Resource Company's qEEG assessment paradigm. Elaboration on what the data reveal is beyond the scope and intent of this chapter. They are intended to be illustrative and show that in the context of integrative practice, neuropsychological and EEG testing can play an important role in establishing baseline individualized norms for neurocognitive functioning and for comparative purposes (e.g., pre- vs. post-intervention, for determining the effects of a drug on neurocognition and brain functioning).

Obviously, extensive training is required before one can competently utilize EEG as an assessment and intervention modality (combined with neurofeedback). It is, however, recommended that in cases of ADD, cognitive/learning disorders, and traumatic brain injury/concussion and whenever psychotropic intervention is involved, referrals should be made to practitioners who are trained in EEG. The application of qEEG can also be extended to depression and anxiety disorders.

Overview of Integrative Assessment

Procedures 1–4 are the core assessment modalities of the CP-C. The initial intake tests are relatively low tech and can and should be used by all practitioners regardless of theoretical orientation or whether one is a physician (psychiatrist), psychologist, or allied mental health practitioner. The HRMTP PHO measures (procedure 1) were found to be central to patient assessment on the basis of their known intimate association with key mind-body processes that underlie psychophysiological disorders, including anxiety/phobias, ADD/HD,

Figure 31.3 Summary overview of neuropsychological test results with brain anatomical and regional localization.

From *International Brain Database Project*, by Brain Resource Company, 2009, Sydney: Author.

cognitive/performance deficits, and depression, to name a few.

Stress responding (procedure 2), the HRV measures taken during the S7s backward-counting task, has emerged as a reliable predictor of ANS reactivity to stressors in clinical and performance contexts (Lehrer, Vaschillo, & Vaschillo, 2000; Malik & Camm, 1995). It should be used to criterion reference PHO measures with an actual psychophysiological response (HRV). As previously mentioned, it is especially useful when PHO profiles are more ambiguous (e.g., M-M-M), and for validating the existence of ANS responses predicted on the basis of PHO measures to reduce the frequency of false-positive and false-negative results that can occur with self-report instruments. HRV can also be monitored continuously over the course of psychotherapy (see chapter 2).

Neuropsychological testing (procedure 3) for initial screening purposes can be done fairly easily with the Brain Resource Company's Internet-based test battery. It provides a snapshot of neurocognitive functioning that

appears particularly relevant for establishing whether ADD is evident, as well as determining the extent to which cognitive functioning may have been affected by any number of medical and psychological disorders. Red-flagged deficits should be further investigated if they are deemed to be of major clinical relevance. This can be done through a full qEEG (procedure 4) evaluation and requires a referral to an appropriately trained practitioner.

Within an integrative diagnostic and intervention model, test procedures and treatment modalities should always be viewed with suspicion, the motto being "Show me the data." While the above procedures mark a step up in the evidence hierarchy, ultimately all test measures and interventions must be viewed with caution. Their predictive validity and efficacy must be established on the basis of longitudinal repeated measures that are derived from ecologically valid situations and settings. Consequently, central to integrative approaches such as the CP-C are outcome studies of

Figure 31.4 Normative significance of neuropsychological test scores.

From *International Brain Database Project*, by Brain Resource Company, 2009, Sydney: Author.

patient responding that are ongoing throughout a therapeutic relationship.

METHODOLOGY: DETERMINING PREDICTIVE VALIDITY AND OUTCOME

In contrast to group studies, which are primarily concerned with intergroup mean differences in responses,

intraindividual investigations seek to establish psychological and psychophysiological tendencies over time in a single person. Although group findings may guide clinical decision making, one can never be certain that mean response parameters that lead to treatment recommendations will be exhibited by every patient, nor can one expect that predictions from an assessment instrument that was validated through group factor analyses will hold up at the level of the single case. Therefore,

1. EEGs Eyes Closed

1.1 Raw EEG Data - Eyes Closed

From *International Brain Database Project*, by Brain Resource Company, 2009, Sydney: Author.

the CP-C subscribes to and recommends that every patient be treated individually. While lip service is often paid to the “evidence-based individualized approach,” the ultimate benchmark of an individualized approach is active engagement in predictive validity and intervention efficacy studies for each individual patient.

This requires the acquisition of multiple repeated predictor and criterion measures over the course of delineated evaluation and treatment periods. This can be difficult when predictor measures are derived from self-report instruments that cannot be retaken each time a patient is seen and evaluated.² For example, one might assume that a PHO measure or profile will predict certain response tendencies because group studies have established specific relationships between, say, HS-N-RC and certain outcome measures. However, the extent to which such a group finding-based assumption will hold up at the individual level still needs to be established. Hence, while group-based information/predictions can be used for clinical guidance, they must be validated in the context of concurrent and criterion referenced measures for determining more precisely

whether a prediction that is based on a one-time-only measurement occasion remains consistent longitudinally. Consequently, in order to ascertain, for example, if high N, in a specific individual, indeed elicits elevated SNS activity, as, for example, reflected in heightened VLF-HRV activity over time, a longitudinal, repeated, and ecological measurement design at the intraindividual level would need to be carried out to validate a diagnosis of high N derived from self-report.

A CP-C outcome study with longitudinal repeated measures in a youth baseball player with ADD is presented to illustrate the single-case clinical diagnostic and intervention process. This patient underwent procedures 1–3 above. His PHO profile was M-L-M, a more ambiguous constellation of HRMTP-PHO subject variables that would not necessarily lead one to suspect ADD or anxiety disorders (see Figure 31.8). Note that this individual was assessed by the Carlstedt Subliminal Attention, Reactivity, and Coping Scale–Athlete Version (CSARCS-A), the athlete analogue of the HRMTP clinical scales (SSHS-C/TAS-EPI and MC). The CSARCS-A exhibits high convergent and discriminant validity with its clinical analogue measures and was found to have more face validity, making it more amenable to subsets of athletes who may be put off by questions that seem irrelevant to sport performance and lead them to engage in response sets that could contaminate their results.

2. The patient's familiarity with a test precludes daily administration. Test-retest reliability is usually established on the basis of alternative-form tests that measure the same construct or readministering a test months later.

Figure 31.6 Overview of qEEG brain mapping of cortical responses to presented stimuli.

From *International Brain Database Project*, by Brain Resource Company, 2009, Sydney: Author.

Adapting the SSHS, TAS, EPI, and MC to athletes appears to have been beneficial, since the favorable convergent validity of the CSARCS-A has allowed for reliable clinical extrapolations within a nonclinical population.

While the CSARCS-A PHO profile in Figure 31.8 was not revealing in the context of ADD, this individual's Web-Neuro battery revealed numerous neurocognitive deficits that would support a diagnosis of ADD (see Figure 31.9).

These neurocognitive deficits will not be elucidated. However, they were noted in the context of performance and a longitudinal investigation of this baseball player's ability to benefit from an intervention that was designed to facilitate attention and reaction time when he is batting. Knowing that this individual was diagnosed as having ADD is of interest, but since the diagnosis was based on temporally isolated testing and evaluative occasions, it may not be conclusive (see discussion of

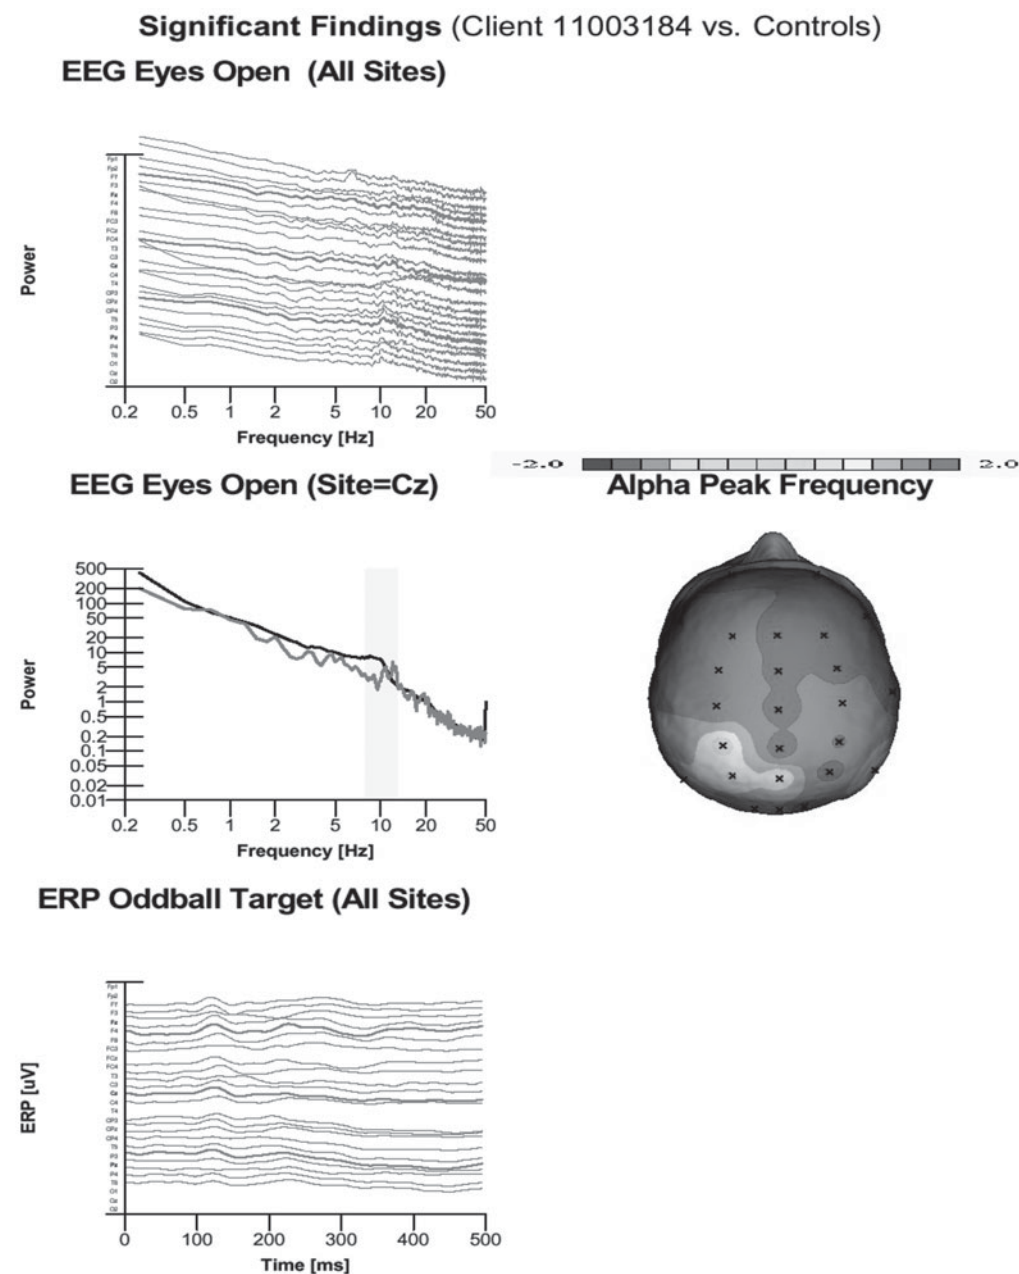

Figure 31.7 Additional qEEG findings.

ADD diagnostic oversights and limitations in chapter 1). Of greater interest, in light of the suspected ADD, is the extent to which this client could indeed attend or focus at a high level and hit a baseball, ecological performance tasks that test one's motor control and reaction time. Actual performance statistics can take precedence over test findings that have poor ecological validity when the

clinician is deciding whether to make a diagnosis, of, for example, ADD, a disorder that can selectively manifest itself (Carlstedt, 2008).

In this case (and most cases) in which self-report and other behavioral instruments are used in the diagnostic process (temporally isolated test occasions), other measures and ecological contexts may be more

CSARCS-A

Carlstedt Subliminal Attention, Reactivity and Coping Scale

Client: CARL-SQFRE-00054

The Carlstedt Subliminal Attention, Reactivity, Coping Scale-Athlete Version (CSARCS-A) contains measures that reflect the following neuropsychophysiological processes (Mind-Body processes):

- I. **Subliminal Attention (SA):** this measure reflects an athlete's subliminal or unconscious focusing or concentration tendencies. It can be viewed as the "Zone" facilitator in athletes who score high on this dimension (23-35). They possess an enhanced ability to focus intensely on task-relevant activities (sport-specific action/movement, etc). Paradoxically, low SA can also be performance facilitating.
- II. **Subliminal Reactivity (SR):** this measure reflects an athletes subliminal autonomic nervous system or "fight" or "flight" tendencies. It can be viewed as the "Great Disrupter" of peak performance in athletes who are high on this dimension (16-25). They are likely to exhibit increased psychophysiological reactivity (nervousness; muscle tension) that is mediated by catastrophic and negative intrusive thoughts, especially during critical moments of competition.
- III. **Subliminal Coping (SC):** this measure reflects an athletes subliminal or unconscious ability to fend off negative intrusive thoughts associated with high Subliminal Reactivity. It can be viewed as the "Great Facilitator" of "Zone" states and peak performance in athletes who are high in this measure (22-34).

Measure	Client Score	Range
Subliminal Attention	18	Medium
Subliminal Reactivity	2	Low
Subliminal Coping	17	Medium

This client has a "**Neutral to Positive**" profile as measured by the CSARCS-A.

It should be noted that the above measures interact to affect performance as a function of the criticality of a competitive moment. In other words the more critical the moment as established by the Carlstedt Critical Moment Analysis System (CCMAS) the greater the probability that an athlete's combination of the above measures will influence performance either positively or negatively. In isolation and outside the context of critical moments or competitive stress singular measures are expected to exert their positive effects. Their negative influences will remain relatively dormant until actual or perceived critical moments or competitive stress are encountered (see Critical Moments During Competition: A Mind-Body Model of Sport Performance When it Counts the Most; Carlstedt [2004] Psychology Press for a complete analysis of the dynamics of the above constructs).

Follow-up Report Service: It is recommended that athletes, coaches and practitioners who use this test battery consult with Dr. Roland A. Carlstedt to further inform the interpretation and implementation. Contact: RCarlstedt@americanboardofsportpsychology.org or DrRCarlstedt@aol.com. See the website: www.americanboardofsportpsychology.org

revealing and reliable, including measures of HRV that are obtained prior to specifically delineated or operationalized tasks or performance actions. For this individual, heart activity was monitored prior to each at-bat during official real baseball games to determine to what extent HRV was associated with or influenced outcome (quality of at-bat; i.e., batting performance).

Relevant data were then entered into an SPSS spreadsheet for later analysis (see Figure 31.10). This methodology can be adapted for more classic clinical situations, for example, monitoring HRV in a panic disorder patient when he or she encounters an induced-structured stimulus (but unknown to the patient), and then determining the time to return to a more homeostatic baseline state. Rather than just teach patients an intervention

and sending them on their way in hopes that they will successfully apply it the moment they sense the onset of panic, a more ecologically structured and controlled paradigm replete with repeated HRV and performance outcome measures is preferred for assessing intervention efficacy. Paradigm adaptations are virtually unlimited, but they should be monitored and analyzed.

What is gleaned from such an analytic approach is illustrated in Figure 31.11. These findings emanate from the data set on HRV and quality of at-bat performance of the baseball player client. Briefly, one can observe that in the pre-intervention assessment phase (i.e., before mental training), on over 31 measurement occasions heart rate was negatively associated with quality of at-bat ($r = -.40$), accounting for about 16% of the

SPSS Processor is ready

Figure 31.10 SPSS spreadsheet with HRV and outcome measures of youth baseball player with ADD.

variance in this outcome measure. This is quite high, considering how far removed such a measure (HRV) appears to be from actually hitting a ball. In this case the greater the heart rate, the worse the performance was. By contrast, SDNN (heart-rate variability index) was positively correlated with performance, suggesting that the psychophysiological resiliency that is associated with this ANS parameter may facilitate performance. Total ANS power was also associated with better performance, a finding that is difficult to interpret.

By contrast, one can see that during the intervention phase (mental training), on 60 measurement occasions, the HRV index (SDNN) and total ANS power and low-frequency ANS activity were positively correlated with quality of at-bat. While, ultimately, the goal of mental training is to improve functioning and performance or reduce symptoms, the mechanisms of doing so are rarely captured as in these data and findings. In addition to achieving the goal of improving batting performance (as

reflected in Figure 31.11) through the application of an intervention that is conceptually linked to dynamics of attention, physiological reactivity, cognitive/strategic planning, and mental coping, which can be monitored and observed in real time and manipulated to induce known individualized parameters of optimum ANS functioning that are associated with positive outcome, treatment can be elevated to a greater level of evidentiary value.

In the case of this client, thought to have ADD, a disorder that is associated with a variety of cognitive deficits that may impede performance, rather than speculate that lack of concentration or inability to engage in facilitative strategic planning may be at the root of his poor batting statistics prior to the intervention, a practitioner, using such an approach, can instead hone in on specific neuropsychophysiological markers (HRV in this case) that can be monitored, assessed, and manipulated repeatedly (one every task occasion) to arrive at an individual's zone

Figure 31.11 Performance and mind-body change as a function of mental training.

of optimum functioning (Hanin, 1980). Here it is possible to observe how the intervention (respiratory sinus arrhythmia/HRV, or RSA/HRV, biofeedback) resulted in heart-rate manipulation to the extent that it no longer negatively affected performance. Instead, this form of biofeedback appeared to facilitate heart-rate deceleration, a linear slowing of each successive cardiac cycle leading up to action (orienting response; Solokov, 1963), which is associated with greater heart-rate variability (SDNN) and better reaction time and performance.

Using this recommended methodology, one is able to capture neuropsychophysiological dynamics that are associated with pre-intervention functioning and per-

formance (symptoms in more classic strictly clinical paradigms) and determine the extent to which an intervention is having an impact, not only on the basis of subjective clinical impressions, intuition, or patient feedback, but as revealed through objective context-appropriate statistical outcome measures that reflect underlying mediating mind-body responses.

In the case of this youth baseball player diagnosed as having ADD, rather than assume the validity of such an assessment and possibly stigmatize him and make extrapolative predictions about how he might perform, the clinician used the individualized longitudinal repeated-measures design, which allows predictor variables to emerge on the basis of conceptually

sound and sensitive outcome measures. With this individual, it was revealed that functional ANS tendencies were associated with both negative and positive performance and that an intervention was associated with enhanced performance, possibly by eliminating the detrimental effects of a specific HRV response (heart rate).³ These dynamics would not have been revealed on the basis of cursory knowledge alone, for example, simply the knowledge that this individual has ADD.

Issues and perspectives relative to this methodology will be readdressed in a more straightforward clinical example below. RSA/HRV biofeedback will also be revisited.

INTERVENTION: INTEGRATIVE APPROACHES TO TREATMENT

The perspective that virtually all psychological/psychiatric disorders and behaviors have neuropsychophysiological consequences has been advanced throughout this book. This central tenet of the HRMTP and the CP-C needs to be considered by all practitioners and move them to utilize mind-body monitoring procedures during initial intake and psychotherapy sessions and especially *in vivo*, in the real-world context of tasks and stressors that patients encounter on a daily basis. Clinicians should remove barriers to doing so by either referring patients to clinicians who are trained in specific high-tech procedures or collaborating directly with capable professionals in-house.

Clinical philosophy or orientations should also not subvert or undermine efforts to glean as much objective information on a patient as possible. There are few, if any, credible reasons why, for example, a psychoanalyst—or any mental health practitioner, for that matter—should let specialty-endemic approaches to interventions, including psychoanalysis, CBT, or client-centered therapy, to name a few, get in the way of ancillary and parallel-concurrent monitoring and analysis of patient responding. Indeed, one could argue that it is unethical not to engage in some of the previously mentioned assessment procedures, especially when one encounters patients with suspected psychophysiological disorders such as anxiety, depression, and ADD.

RSA/HRV Biofeedback

Relative to interventions, many of the same pre-intervention monitoring, assessment, and analysis procedures should be applied in the treatment phase of the clinical process. The key intervention in the CP-C is RSA/HRV biofeedback, since it is ideally suited for directly addressing known ANS disturbances that have been documented (validated) in most psychophysiological disorders (e.g., anxiety/panic disorders, phobias). RSA/HRV biofeedback is a potent and quick procedure for immediately virtually restoring ANS balance or homeostasis and has been shown to actually shut down full-blown panic attacks (Gervirtz, 2000).

Specific HRV parameters are also sensitive measures of overall physical status and can reflect mental states. For example, the SDNN measure, also known as the HRV index, can reflect fitness and cardiovascular resiliency, with a reading of under 30 associated with increased risk for cardiac arrhythmia and even sudden death (Malik & Camm, 1995). Severely depressed individuals are also likely to exhibit depressed HRV. VLF-HRV and low/high frequency (L/H) ratio also are associated with certain HRMTP-PHO profiles and singular measures, including independent high N.

The monitoring of select individuals with more vulnerable PHO profiles and certain psychophysiological disorders in real time via telemetry instrumentation can capture excessive ANS response tendencies that would be expected as they occur. Importantly, using HRV monitoring over time for mind-body assessment purposes and customizing individualized RSA biofeedback protocols allow for the evaluation of change or therapeutic progress, longitudinally.

Again, such procedures can be employed irrespective of one's psychotherapy approach or system. In other words, even if a practitioner uses CBT or insight therapy as a primary intervention technique, HRV monitoring and RSA biofeedback can and should be used to assess treatment progress as well as augment therapy with a procedure that exerts a direct effect on neuropsychophysiology that can be immediately observed and manipulated. Practitioners who attempt to treat patients with chronic and/or acute underlying dysfunctional mind-body response tendencies (which can affect morbidity and mortality) without awareness of their functional parameters (through monitoring procedures) may be providing incomplete services. In an era in which relevant neuropsychophysiological systems can be illuminated technologically during the diagnostic and intervention process, often in ecological, real-time situations and settings, it is no longer tenable to merely assume that an intervention is inducing positive change or

3. Heart activity is associated with both efferent and afferent cortical (brain) connections, along with blood pressure-regulating mechanisms via the baroreceptors in the neck, which may be involved with attentional and cognitive processing, and indirectly, performance and could play an overlooked role in ADD dynamics (see Andreassi, 1995)

symptom amelioration. Patients who, for example, see a neurologist or orthopedist for chronic pain symptoms or a psychotherapist for depression and are prescribed medication or attempt to engage in whatever intervention modality the practitioner that they happened to seek out recommends may not experience relief for comorbid conditions that occur parallel or ancillary to a primary complaint. In such cases, pain and mental distress are addressed, yet underlying ANS activity of cardiologic significance, which may be mediated by both pain and depression, goes unnoticed. The following case overview provides an example of what can be overlooked by medical and mental health clinicians who address symptoms but fail to take into account concomitant “damage” that may not be readily apparent when they are treating pain, depression, or a host of other conditions that involve collateral subliminal mind-body processes that are at work contributing to the development of other diseases and disorders.

Figures 31.12, 31.13, and 31.14 reflect the HRV profile of a patient with severe depression exacerbated/mediated by chronic pain and sporadic cognitively induced anxiety attacks (spontaneous negative intrusive thoughts, visions of an on-the-job accident leading to herniated disks, PTSD-like flashbacks).

Note this patient’s baseline SDNN (20) (see Figure 31.12). An HRV index this low is indicative of reduced physical activity that would be expected in someone with chronic back pain. Severe depression probably exacerbated her reduced HRV. Looking at her HRV profile, independent of any knowledge about this patient’s clinical background, an informed cardiologist or physician might suspect an underlying cardiologic disorder (Malik & Camm, 1995). A mental health practitioner or general psychotherapist—and most physicians, for that matter—would likely never see such a chart (HRV is rarely used as a screening utility in mental health settings) or consider HRV as a diagnostic option in what appears to be a chronic pain patient with depression. That is unfortunate, considering the potency of HRV as a predictor measure and diagnostic tool (Malik & Camm, 1995). For example, in the second measuring condition (see Figure 31.13), the patient was asked to imagine or cognitively induce negative imagery of an accident that she experienced⁴ This resulted in a significant increase in ANS-SNS reactivity (from L/H ratio of 2.1 at baseline to 4.3 in the cognitive-imagery stress condition). An imagery stress condition is likely to lead

to elevations in HRV-SNS activity in patients who are high in HS, high in N, and low in RC and can be substituted for the serial 7s backward-counting test to assess ANS reactivity tendencies. Although one might assume that a mental task that re-creates negative images will lead to strong emotions, it is preferable to document mind-body responding (to confirm such) on the basis of a neuropsychophysiological correlate such as HRV. Doing so also helps guide eventual intervention and determine treatment efficacy.

For this patient, RSA-HRV biofeedback was attempted as an intervention secondary to medication prescribed by a neurologist. The result of the initial treatment session (first 2-minute epoch) can be seen in Figure 31.14. Here we observe a reduction in SNS activity from baseline and imagery conditions level (L/H of 1.1). While her attempts to induce the desired RSA wave that can be seen in Figure 31.15 were only partially successful, her breathing patterns were sufficiently positively changed to reduce her ANS hyperreactivity, which was associated with heightened stress. People who are high in neuroticism (like this patient) have the most difficulty learning positive breathing patterns (see Figure 31.15). For example, an athlete with competitive anxiety was, unlike the previous patient, and despite his high level of neuroticism, able to induce a strong ANS shift to a parasympathetic predominant state, a response that is associated with a reduction of stress and increased relaxation. One cycle of RSA-HRV biofeedback, if timed to correspond with pre-action phases of most sport-specific tasks, is associated with heightened focus, faster reaction time, and better performance, all of which make this an ideal intervention for athletes with ADD and anxiety issues (Malik & Camm, 1995).

In light of HRV-RSA monitoring and biofeedback’s emerging potency as a diagnostic tool and intervention modality, it needs to be integrated into the patient evaluation process and utilized as a primary treatment modality for most, if not all, psychophysiological disorders, including refractory-essential hypertension, panic disorder, and depression and to enhance performance (Moss, McGrady, Davies, & Wickramasekera, 2003).

Neurofeedback

Neurofeedback (NF) is an ancillary procedure in the CP-C, in which a client or patient views a computer screen while wearing an electrode cap or a few electrodes that are placed over specific brain sites.⁵ Select

4. The patient’s HRMTP-PHO profile of HHS-HN and LRC makes her an ideal candidate for imagery- and hypnosis-based interventions; hence the negative imagery condition to test stress-response tendencies (self-induced stress through visions of a previous accident).

5. For more information on neurofeedback, contact the International Society for Neurofeedback and Research (<http://www.isnr.org>).

locations are then targeted for shaping or manipulation in a direction (frequency range and amplitude) that is thought to be conducive to enhancing performance or reducing/eliminating symptoms. Its greatest utility and strongest body of supportive research lies in the area of ADD, although it can be and has been used in attempts to treat a number of conditions that have strong cortical components, including traumatic brain injury and stroke, depression, anxiety, and obsessive-compulsive disorder (International Society for Neurofeedback and Research, 2009; Moss et al., 2003). Essentially, individuals undergoing neurofeedback learn through positively reinforced subliminal operant responses to entrain brain-wave frequencies and amplitudes in certain cortical areas that are associated with optimum functioning, well-being, and mental health (see Figure 31.16).⁶

The CP-C approach to NF is unique since it can only be applied in the context of the methodological, ecological, and temporal stipulates of its assessment, intervention, and outcome efficacy paradigm. The rigorous demands of engaging in a protocol based on longitudinal, ecological, and repeated measurement preclude administration of any intervention, especially NF, in a cursory manner (e.g., structuring NF to accommodate economic and temporal limitations that are often inherent to most practice settings rather than adhere to a rigorous evidence-based NF protocol that is crucial to the accuracy of assessments and establishing the efficacy of NF procedures). Consequently, the utility of NF can be immensely constrained or it can be taken out of consideration as a viable treatment modality for patients/clients and practitioners who have limited available time to engage in intervention that, to date, does not have established (validated) temporal guidelines for dosage and duration (Matthews, 2008).

Assuming that patients/clients are able to engage in or practice NF under experimental conditions that are free of arbitrary temporal and other clinical constraints, the probability of enhancing performance and functionality and eliminating or reducing symptoms is expected to increase. As such, NF has much potential, but it should

Figure 31.16 Neurofeedback with qEEG monitoring.

always be applied with caution and skepticism and within a sound methodological and analytic framework.

A promising guiding theory for NF is the transient hypofrontality hypothesis (THH; Dietrich, 2006). It proposes that so-called zone states occur as a function of the reallocation of cortical resources away from the prefrontal cortex in response to aerobic effort and the progression of time. While intended to illuminate and delineate cortical dynamics of exercise and its impact on cognition, by extrapolation and in light of the expedited impact that NF can exert in mediating immediate neuronal changes, the THH provides a highly plausible conceptual framework for guiding NF.

Central to a THH-based NF protocol is the manipulation of frontal/prefrontal activity, specifically, reduction of higher beta frequencies and related amplitude (reinforcing reductions over select F electrode locations; see 10–20 system) and increasing beta activity in the motor cortex region. In an ecological exercise paradigm using telemetry EEG, Carlstedt (2008) demonstrated reductions in frontal lobe and increases in motor cortex activity (total power = all EEG activity) as a function of the progression of time (see Figures 31.17, 31.18, and 31.19). Based on these findings from the first EEG investigation of the THH, it is hypothesized that the most expeditious means for achieving reduced activity of the frontal lobe (the seat of planning, volition, critical-analytic, and associated negative cognitions) in the presence of ADD, depression, anxiety, OCD, and most (if not all) executive-based psychological disorders may be through NF. Since frontal lobe activity has also been associated with performance disruption, an NF protocol that attempts to reduce activity in this brain area may also be beneficial for athletes and performers (Dietrich, 2006).

6. While neurofeedback is applied by thousands of practitioners, it still is not considered a mainstream or universally accepted intervention, especially in the medical community, which has argued that since gold-standard investigations have, to date, failed to validate the vast majority of location-, frequency-, and amplitude-based neurofeedback protocols, they cannot be credibly applied. Proponents of this modality counter this argument with the assertion that traditional randomized, double-blind, placebo-controlled studies cannot be the gold-standard benchmark for a treatment procedure that is designed to help individual patients. It has also been asserted that pharmaceutical companies and the field of medicine have a vested political interest in undermining the advancement of this and other intervention procedures that could affect their revenue streams and power status in the allied mental health arena. These pros and cons will not be debated here (see International Society for Neurofeedback and Research, 2009).

Figure 31.17 Early phase of telemetry-based test of the THH using the Mind-Media NEXUS-32 system.

The CP-C NF paradigm also stresses ecological assessment; if possible, telemetry-based EEG should be used to better illuminate brain activity in context-relevant settings and situations and in response to specific performance-relevant tasks. An active-ecological qEEG brain mapping serves as the basis for eventual sit-down/in-office or actual in-the-field ecological NF sessions (see Figure 31.16).

As always (although this is frequently ignored or overlooked), any intervention protocol, including ones that use NF, regardless of the strength of its conceptual foundation, guiding theory, and research findings (support), must be validated in the context of longitudinal, ecological and repeated outcome measures that reveal performance gains or a reduction/elimination of symptoms and/or concomitant neuropsychophysiological responses that are associated with a return to autonomic and/or cortical balance, at the level of the individual, before it can be deemed efficacious.

Hypnosis

Hypnosis as an intervention involves induction of a state of altered consciousness and cognitive responding

in an attempt to enhance stimulus-specific awareness, modify maladaptive negative, or reinforce positive behaviors and/or disengage pain/symptom mechanisms. It is ideally suited to individuals who are high in HS (see chapter 9), and while practitioners who specialize in hypnosis claim it can be successfully used by anyone, neurophysiological evidence has revealed clear differences between people depending on their level of this psychophysiological trait (Crawford & Gruzelier, 1992). This method will not be elaborated here, since another chapter in this book is devoted to this topic. It should be noted, however, that hypnosis can be a potent intervention modality for the right individual; this points to the need to assess patients and clients for HS to increase treatment amenability, compliance, and efficacy.

Cognitive-Behavioral Methods

Cognitive-behavioral therapy (CBT) and numerous hybrids thereof have become the most pervasive intervention approach in evidence-based psychotherapy since they are fairly straightforward and easy to administer (Wright, Basco, & Thase, 2005). This approach claims strong evidence that supposedly attests to its efficacy.

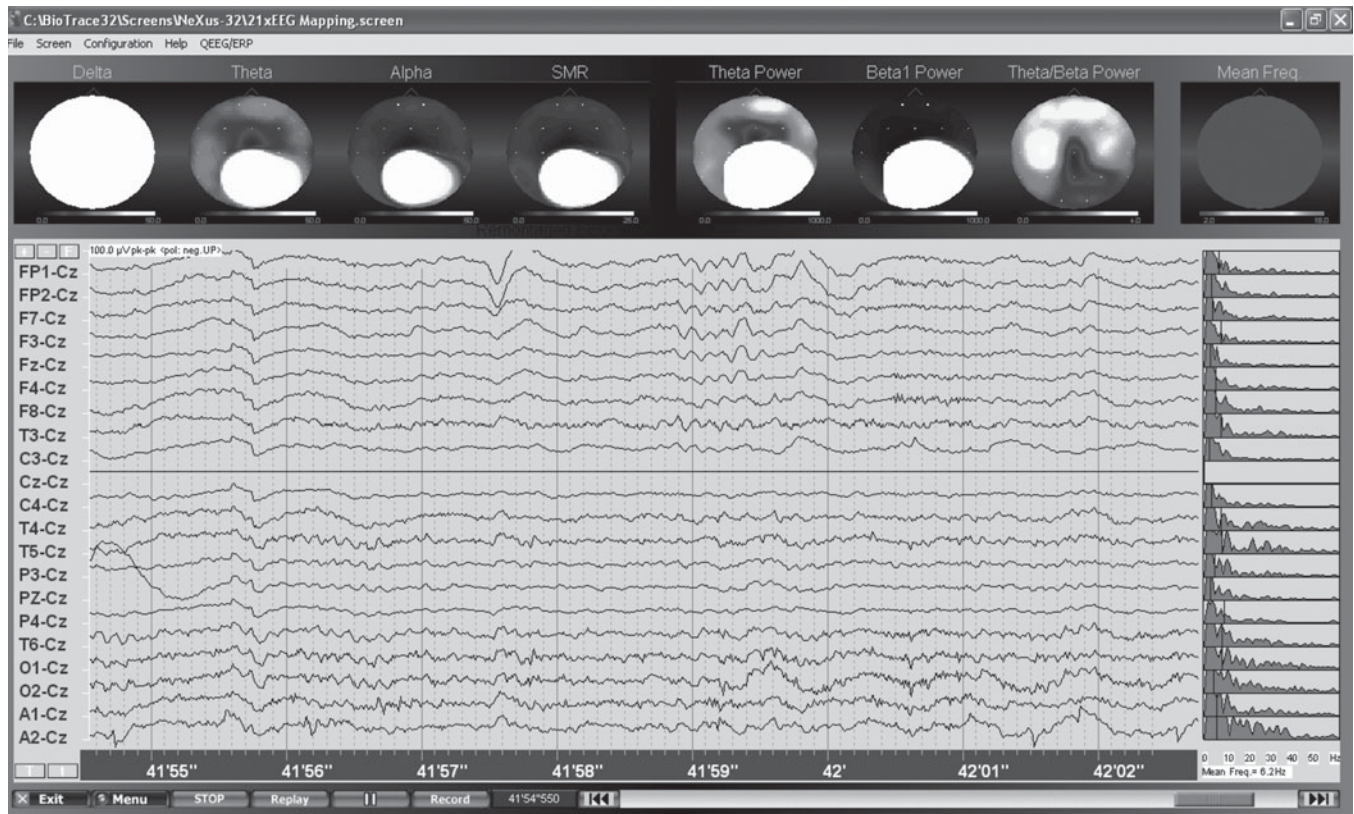

Figure 31.18 Later stages of test of THH.

While such claims may have credence, it should not be assumed that because large trials have found it to be effective, every individual will benefit from this form of treatment. CBT, like all interventions, should be tested as prescribed to determine its efficacy.

INTERVENTION EFFICACY TESTING METHODOLOGY

Intervention efficacy testing involves acquiring ecological, longitudinal, and repeated measures at the intraindividual level to establish the extent to which a treatment modality is able to enhance performance and health facilitative behaviors or reduce/eradicate symptoms, illnesses, and/or mental dysfunction. It involves identifying independent/predictor variables (usually personality traits, behaviors, and/or neuropsychophysiological measures) and repeatedly monitoring or measuring them over time in multiple settings and situations, including ecological (real-world) conditions that are likely to lead to the appearance of stressors or evocative stimuli that lead to the manifestation of symp-

toms, illness, and/or maladaptive mind-body responses and, in some cases, adaptive or protective responding that can be quantified (dependent/criterion outcome measures). For example, to determine the effects of hypnosis or CBT, patients would engage in an intervention session that is monitored in terms of, for example, depth of hypnosis or strength of CBT response (e.g., thought stoppage or switching) along with concomitant HRV parameters (predictor/independent variables). They would then be sent into an ecological situation that is known to contain stressors or stimuli that need to be countered or dealt with (e.g., an airplane or an elevator). Patients' subsequent responses would then be evaluated on the basis of behavioral observations and neuropsychophysiological responding and compared to baseline (patients' responses while practicing hypnosis or engaging in CBT in an innocuous office setting). The latter measures would serve as dependent/criterion variables. The ultimate goal of such a methodology is to determine the degree to which an intervention actually leads to positive mind-body changes that are associated with adaptive ANS responses, resulting in a documentable reduction in symptoms or enhanced behaviors

Fold Function

Figure 31.19a Statistical “Fold” function depicts differences between first and last 5 minutes of EEG activity during stationary bike experiment (photo). Note decrease in FP1 activity (pre-frontal cortex total power) and increase in total EEG power over C3 (motor cortex area).

Figure 31.19b Telemetry-EEG experiment THH.

(e.g., countering or facing a fear repeatedly) or improved performance (see Figures 31.12 and 31.15).

Comprehensive Database Creation and Management

Structuring interventions that contain longitudinal efficacy testing components requires the creation, development,

and management of databases that document assessment (independent/predictor) and outcome/treatment variables. They are used for comparative purposes over time and are critical for determining intervention amenability, compliance, and overall effectiveness (see Figure 31.10).

Databases should also contain psychological performance statistics. These can be generated through the operationalization of behavioral and mind-body measures to reflect outcome or change as a function of an intervention or functional differences in an assessment paradigm. Measures that have been conceptually linked to specific outcome variables can be used to determine their effects on an intervention. For example, when using RSA-HRV biofeedback to reduce anxiety symptoms associated with, for example, riding on an elevator, one could attempt to ascertain the effects of VLF-HRV activity on the quality of an intervention (outcome measure). In this specific case, it would be expected that a reduction in symptoms would be associated with less VLF during the intervention than during a stress test or initial encounter (prior to the intervention) with a real-world anxiety-evoking stimulus (when frequency would be expected to rise) and would lead to subsequent successful behaviors, such as overcoming an in-the-moment fear of riding on an elevator. The above

conditions would be repeated numerous times until outcome parameters/measures stabilize (assuming that they will eventually), which would be associated with a high psychological, behavioral, or mind-body proficiency quotient (PPQ, BPQ, or MBPQ).

To illustrate, in an attempt to treat the above phobia, a patient would be exposed to the anxiety-evoking condition (entering an elevator). Each attempt to enter and successfully ride the elevator would be associated with an ANS-HRV response profile. Over time this mind-body response profile would, in a successful scenario, change and should exhibit a reduction in VLF-HRV activity as a function of RSA/HRV biofeedback and allied cognitive procedures. The time to stabilize as reflected in HRV profile changes and successful attempts to enter and ride the elevator while maintaining ANS balance would reflect a patient's PPQ, BPQ, or MBPQ, depending upon what predictor/independent variable is being expressed. In a case where 20 attempts were required to achieve success (successful elevator ride), a patient's PPQ/BPQ would be .05. Retesting a week later might reveal success after 2 attempts and would result in a PPQ/BPQ of .50. An MBPQ would be expressed in change between baseline and worst stress response to the evoking stimuli (elevator) and successful mastery of the anxiety-inducing condition (elevator) as a function of successful behavior. Thus, if VLF activity at baseline were 19 and 85 in the stress condition and 15 during RSA/HRV biofeedback during a successful ride on the elevator, the MBPQ would be expressed as +70 (positive gain or reduction of maladaptive response [VLF] by 70 units in successful condition and +4 compared to baseline, indicating less ANS reactivity in the stress condition (VLF of 15) than in an innocuous baseline setting (VLF of 19; less indicating a positive gain or response).

This system allows for the quantification of the diagnostic and intervention process, something that is rarely done but should be a part of all intervention pursuits.

Comprehensive Report

The culmination of assessment and intervention analyses and efficacy testing is a comprehensive report that is designed to convey to patients, clients, or colleagues, in language and terminology that are understandable, the clinical status of an individual (see Figure 31.20).

THE UNIVERSAL CLINICAL TRIAL

The universal clinical trial is a nonfunded, non-institutionally sponsored initiative to enroll clinicians, espe-

cially those who are in private practice, in an assessment and/or intervention efficacy testing investigative project that uses select diagnostic/assessment components of the CP-C and HRMTP-PHO subject variables. This project was designed not to question or usurp practitioners and a particular system of psychotherapy that may specialize in but rather to attempt to motivate practitioners, regardless of their training background, specialty, or practice orientation, to augment their approach to testing and intervention with specific assessment, monitoring, and efficacy testing methods and procedures that are designed to better document and analyze the diagnostic and intervention process.

Practitioners can commit to utilizing any of the following assessment, monitoring, and intervention tests, instruments, and procedures. Data from each would be acquired, managed, stored, and transmitted to a central database repository for analysis, and a report would be provided to the participating clinician.

Level 1: Gold Standard

Tests: Tellegen Absorption Test, Positive Affect–Negative Affect Schedule/Eysenck Personality Inventory or Neuroticism Scale of the NEO, and Marlowe-Crowne (practitioners who have been trained to administer the Harvard or Stanford Scales of Hypnotic Susceptibility should substitute the TAS with one of these behavioral tests)

Monitoring instrumentation: Biocom Technologies Heart Rhythm Scanner in accord with described methodologies, including the administration of the serial 7s stress test

Methodology and database management: as described above

Level 2: Silver Standard

Tests only: Administration of above tests at intake

Procedures

Practitioners would agree to, at minimum, administer the above test battery. Those who commit to the gold-standard level would purchase the recommended HRV software and engage in monitoring and testing as prescribed and manage all data accordingly.

Training

Practitioners would receive Internet-based training.

CSARCS-A, Cognition, DASS, EI, Personality.

Client: CARL-SQFRE-00043 (birth date 30 Oct 1992; age 13 years; male)

Test	Level	Function Measured	Functional Significance
Carlstedt Subliminal Attention, Reactivity and Coping Scale-Athlete Version (CSARCS-A)			
	Medium	Subliminal Attention	Ability to attain peak performance during critical moments
	Medium	Subliminal Reactivity	
	Low	Subliminal Coping	
General Cognition			
Memory	Average	Working memory recall and recognition	Ability to attend to, learn, remember, store, retrieve and manipulate new information. It includes long and short term memory
Attention, Behavioral	Average	Sustained attention Focussed attention Impulsivity Cognitive flexibility	Ability to selectively concentrate during cognitive tasks, detect and respond to change in the environment, sustain attention over time and control impulses
Sensory-Motor/Spatial	Average	Hand/eye coordination Accuracy of selecting an appropriate response	Ability to perform motor skills and respond to information in a timely fashion. It includes reaction time
Language	Average	Word comprehension Verbal fluency Verbal memory	Ability to recognize words, access words and remember what has been heard
Executive Function	Average	Planning Abstraction Error correction	Ability to plan, strategize, execute complex tasks, abstract thinking, rule acquisition, inhibiting inappropriate actions and ignoring irrelevant sensory information
Emotion Recognition	Average	Emotional expressions	Ability to recognize interpersonal emotions through facial expression
Depression Anxiety Stress Scales (DASS)			
	Normal Mild Mild	Depression Stress Anxiety	Screening for Depression and Anxiety

Deficit ≤ -2 standard deviation

Average > -1 and < 1 standard deviation

Borderline > -2 and ≤ -1 standard deviation

Superior ≥ 1 standard deviation
